Contents of Volume 1	v
List of Contributors for Volume 1	xi
Editorial Board	xvii
Preface	xix

VOLUME 1

Section 1: Metal Matrix Composite Materials, Edited by Manoj Gupta

Introduction to Metal Matrix Composite Materials: An Introduction <i>Manoj Gupta</i>	1
Fundamentals of Metal Matrix Composites <i>Sankaranarayanan Seetharaman and Manoj Gupta</i>	11
An Insight Into Metal Matrix Composites With Micron Size Reinforcement <i>Arsha Antony Geetha, Madhusoodhanan Geethakumari Akhil, Thazhivilai Ponnu Devaraj Rajan, and Ballambettu Chandrasekhara Pai</i>	30
An Insight Into Metal Matrix Composites With Nano Size Reinforcement <i>Massoud Malaki</i>	42
An Insight Into Magnesium Based Metal Matrix Composites With Hybrid Reinforcement <i>Sankaranarayanan Seetharaman, Subramanian Jayalakshmi, Ramachandra Arvind Singh, and Manoj Gupta</i>	52
Metal Based Composites With Metastable/Amorphous Reinforcements <i>Penchal Reddy Matli and Manoj Gupta</i>	78
Development and Properties of Amorphous Particles Reinforced Al Matrix Nanocomposites <i>Adnan Khan, Mattli M Reddy, Penchal Reddy Matli, Rana A Shakoor, and Manoj Gupta</i>	96
Metal Matrix Syntactic Composites <i>Vyasraj Manakari, Gururaj Parande, Manoj Gupta, and Mrityunjay Doddamani</i>	109
Insight Into Layered Metal Matrix Composites <i>Akshay Padnuru Sripathy and Manoj Gupta</i>	121
Eco-friendly Metal Matrix Composites <i>Gururaj Parande, Vyasraj Manakari, and Manoj Gupta</i>	140
Liquid Phase Processing of Metal Matrix Composites <i>Madhusoodhanan Geethakumari Akhil, Kaimanikal Madhurananthan Nair Sree Manu, Thazhivilai Ponnu Devaraj Rajan, and Ballambettu Chandrasekhara Pai</i>	160
Solid Phase Processing of Metal Matrix Composites <i>Mingyang Zhou, Lingbao Ren, Gaofeng Quan, and Manoj Gupta</i>	173
Two Phase Processing of Metal Matrix Composites <i>Penchal Reddy Matli, Tirumalai Srivatsan, and Manoj Gupta</i>	197

Additive Manufacturing of Metal Matrix Composites <i>Sankaranarayanan Seetharaman and Manoj Gupta</i>	209
Severe Plastic Deformation Processing of Metal Matrix Composites <i>Sankaranarayanan Seetharaman, Ankita Mandal, and Manoj Gupta</i>	230
Friction Stir Processing of Metal Matrix Composites <i>VK Bupesh Raja and Manoj Gupta</i>	247
An Insight Into Processing Maps of Metal Matrix Composites <i>Biranchi N Sahoo and Sushanta K Panigrahi</i>	257
Microstructural Aspects of Metal-Matrix Composites <i>Devadas Bhat Panemangalore and Rajashekhara Shabadi</i>	274
Tensile Characteristics of Metal Matrix Composites <i>Milli S Kujur, Ved P Dubey, Ashis Mallick, and Manoj Gupta</i>	298
Tensile Response of Al-Based Nanocomposites <i>Penchal Reddy Matli, Vyasraj Manakari, Gururaj Parande, and Manoj Gupta</i>	313
Compressive Response of Aluminum Metal Matrix Composites <i>Ramanathan Arunachalam and Pradeep K Krishnan</i>	325
Fatigue Behavior of Magnesium Matrix Composites <i>Sravya Tekumalla and Manoj Gupta</i>	344
High-Temperature Properties of Metal Matrix Composites <i>Oluseyi P Oladijo, Samuel A Awe, Esther T Akinlabi, Resego R Phiri, Lebudi L Colliueus, and Rebaone E Phuti</i>	360
Creep Characteristics of Metal Matrix Composites <i>Hong Yang, Sarkis Gavras, and Hajo Dieringa</i>	375
Tribological Properties of Light Metal Matrix Composites <i>Jitendra K Katiyar, Jaafar Al Hammad, and Abdul Samad Mohammed</i>	389
Mechanical and Tribological Properties of Aluminum Based Metal Matrix Nanocomposites <i>Mir Ifan Ul Haq, Sanjay Mohan, Ankush Raina, Subramanian Jayalakshmi, Ramachandra Arvind Singh, Xizhang Chen, Sergey Konovalov, and Manoj Gupta</i>	402
Damping Characteristics of Metal Matrix Composites <i>Penchal Reddy Matli and Manoj Gupta</i>	415
Electromagnetic Shielding Capabilities of Metal Matrix Composites <i>Anisha Chaudhary, Vinay Gupta, Satish Teotia, Subhash Nimanpure, and Dipen K Rajak</i>	428
Corrosion Characteristics of Metal Matrix Composites <i>Devadas Bhat Panemangalore and Udaya Bhat K</i>	442
Coating Technologies for Metal Matrix Composites <i>Sumit Pramanik and Kamal K Kar</i>	454
Biocompatibility of Metal Matrix Composites Used for Biomedical Applications <i>Somasundaram Prasadh, Santhosh Suresh, Vaishnavi Ratheesh, Raymond Wong, and Manoj Gupta</i>	474
Joining of Metal Matrix Composites <i>VK Bupesh Raja and Manoj Gupta</i>	502
High Performance Machining of Metal Matrix Composites <i>Keng S Woon</i>	512
Application of Metal Matrix Composites in Engineering Sectors <i>Dipen K Rajak and Pradeep L Menezes</i>	525

Metal Matrix Composites for Automotive Components in Depth Case Study: Development of Automotive Brake Disc <i>Nanang Fatchurrohman and Shamsuddin Sulaiman</i>	540
--	-----

Application of Metal Matrix Composites in Non-Structural Applications <i>Mubarak Ali M, Mohamed Thariq, Vishwesh Dikshit, and Bhudolia S Kumar</i>	557
---	-----

Section 2: Polymer Matrix Composite Materials, Edited by Dermot Brabazon

Introduction: Polymer Matrix Composite Materials <i>Dermot Brabazon</i>	563
--	-----

Particulate Reinforced Polymer Matrix Composites

Overview of Mechanical and Physicochemical Properties of Polymer Matrix Composites <i>Kai Bin Liew, Choon Fu Goh, Sajid Asghar, and Haroon K Syed</i>	565
--	-----

Processing of Polymers and Their Composites: A Review <i>Jaspreet Singh, Kulwinder Singh, JS Saini, and Mohammed SJ Hashmi</i>	577
---	-----

Tailored Behavior of Polymer Matrix Composite Materials <i>Yousef Tamsilian, Samira Alvani, Fatemeh Abdolkhani, and Elham Khademi Moghadam</i>	604
---	-----

Effect of Particle Size and Content of Crumb Rubber on the Dynamic Properties of Passenger Tyre Tread Using Finite Element Method <i>Adnan A Alshukri, Faieza A Aziz, Mohd S Salit, Nuraini A Aziz, and Mohammed Al-Maamori</i>	615
--	-----

Overview of Surface Roughness Effect on Silver Nanoparticle Filled Epoxy Composites <i>MA Salim, R Hamidi, and AM Saad</i>	628
---	-----

Polymer Single-Screw Extrusion With Metal Powder Reinforcement <i>Rupinder Singh, N Singh, P Bedi, and IPS Ahuja</i>	671
---	-----

Polymer Twin Screw Extrusion With Filler Powder Reinforcement <i>Rupinder Singh, Sunpreet Singh, and Mohammed SJ Hashmi</i>	691
--	-----

The Effect of In-Situ-Formed Silver Nanoparticles on the Morphological Properties of Epoxy Resin Filled Composites <i>MA Salim, R Hamidi, and AM Saad</i>	706
--	-----

Toughening Mechanisms of Devulcanized Rubber Modified Epoxy Based Composites Reinforced With Zirconia <i>Alaeddin B Irez, Emin Bayraktar, and Ibrahim Miskioglu</i>	713
--	-----

Polymer Nanocomposite Characterization and Applications <i>Mahsa Shirazi, Gholamreza Masoudi Rad, and Yousef Tamsilian</i>	725
---	-----

Fibre Reinforced Polymer Matrix Composites

Effect of Fiber Orientation on the Mechanical Properties of Laminated Polymer Composites <i>N Ghamarian, Mohamed AA Hanim, P Penjumras, and Dayang LA Majid</i>	746
--	-----

Tensile Properties of Woven Intra-Ply Carbon/Kevlar Reinforced Epoxy Hybrid Composite at Sub-Ambient Temperature <i>Nurain Hashim, Dayang LA Majid, Danish M Baitab, Noorfaizal Yidris, and Rizal Zahari</i>	766
---	-----

Thermoplastic Composites for Fused Deposition Modeling Filament: Challenges and Applications <i>Kamaljit S Boparai and Rupinder Singh</i>	774
--	-----

Biomedical Applications of Polymer Matrix Composites

Hydroxyapatite Based Polymer Composites for Regenerative Medicine Applications <i>Luis J del Valle and Jordi Puiggali</i>	785
Biopolymer Matrix Composite for Drug Delivery Applications in Cancer <i>Ankit Jain, Madhavi Tripathi, Shiv K Prajapati, and Ashok M Raichur</i>	804
Covalent and Electrostatic Protein-Polysaccharide Systems for Encapsulation of Nutraceuticals <i>Hadis Rostamabadi, Seid Reza Falsafi, and Seid Mahdi Jafari</i>	818
Polymer Matrix Composites Containing Carbon Nanomaterials for Medical Applications <i>Maryam Ahmadzadeh Tofighy, Soha Habibi, and Toraj Mohammadi</i>	832
Biopolymer Matrix Composites for New Medical Applications <i>Zahra Shariatinia</i>	842
Poly(methyl methacrylate)-Based Composite Bone Cements With Different Types of Reinforcement Agents <i>Sanaz Soleymani Eil Bakhtiari, Hamid Reza Bakhsheshi-Rad, Saeed Karbasi, Ahmad Fauzi Ismail, Safian Sharif, Alexander Seifalian, Houman Savoji, and Filippo Berto</i>	867
Hydrogel Composite Films for Wound Healing <i>Ikram U Khan, Huma Mahmood, Yasser Shahzad, Sajid Asghar, and Haroon K Syed</i>	887
Polymer Composites for Organ Reconstruction <i>Haroon K Syed, Sajid Asghar, Kai Bin Liew, Ikram U Khan, Fizza A Razzaq, and Saba Rafique</i>	905
Overview of Additive Manufacturing Biopolymer Composites <i>Bankole I Oladapo, S Abolfazl Zahedi, Vincent A Balogun, Sikiru O Ismail, and Yarjan A Samad</i>	915
Marine Polysaccharide-Based Composite Hydrogels <i>Saad Salman, Syed H Khalid, Ikram U Khan, Sajid Asghar, Fahad H Shah, and Muniba Tariq</i>	929

Other Application Areas for Polymer Matrix Composites

Multifunctional Polymer Matrix Composites <i>Sajid Asghar, Haroon K Syed, Kai Bin Liew, Ikram U Khan, and Saad Salman</i>	937
Polymer Matrix Composite Materials for Aerospace Applications <i>Subramani Devaraju and Muthukaruppan Alagar</i>	947
Tribology of Polymer Matrix Composites Within the Automotive Industry <i>Leonardo I Farfan-Cabrera, Monica Tapia-Gaspar, and José Pérez-González</i>	970
Polymer Matrix Composites Materials for Water and Wastewater Treatment Applications <i>Maryam Ahmadzadeh Tofighy and Toraj Mohammadi</i>	983
Nanomaterial-Incorporated Polymer Composites for Industrial Effluent: From Synthesis to Application <i>Yousef Tamsilian, Mahsa Shirazi, and Gholamreza Masoudi Rad</i>	998

New and Emerging Processing Methods for Polymer Matrix Composites

Additive Manufacturing of Polymer Matrix Composites <i>Farnoosh Pahlevanzadeh, Hamid Reza Bakhsheshi-Rad, Dermot Brabazon, Mahshid Kharaziha, Ahmad Fauzi Ismail, Safian Sharif, Mahmood Razzaghi, and Filippo Berto</i>	1013
New Design Consideration of Polymer Matrix Composite Materials <i>Peng Liu</i>	1029

Thermal and Morphological Analyses of Polymer Matrix Composites <i>Subramani Devaraju, Arumugam Hariharan, Krishnasamy Balaji, and Muthukaruppan Alagar</i>	1038
A New Design of Epoxy Based Composites Reinforced With Devulcanized Rubber, Alumina Fiber and BN <i>Alaeddin B Irez, Emin Bayraktar, and Ibrahim Miskioglu</i>	1069
Development of Low-Cost Graphene-Polymer Blended In-House Filament for Fused Deposition Modeling <i>Rupinder Singh and Ranvijay Kumar</i>	1081
PLA Composite Matrix as Functional Prototypes for Four Dimensional Applications <i>Sudhir Kumar, Rupinder Singh, Tajinder P Singh, and Ajay Batish</i>	1091
Extrusion-Based Additive Manufacturing Techniques for Biomedical Applications <i>Ghazal Tadayyon, Daniel J Kelly, and Michael G Monaghan</i>	1101
Preparation and Applications of Synergically Combined Polymer Matrix Composites <i>Shashank T Mhaske and Arjit Gadgil</i>	1112

LIST OF CONTRIBUTORS FOR VOLUME 1

Fatemeh Abdolkhani
Shahid Chamran University of Ahvaz, Ahvaz, Iran

I.P.S. Ahuja
Punjabi University Patiala, Patiala, India

Madhusoodhanan Geethakumari Akhil
Council of Scientific & Industrial Research, National Institute for Interdisciplinary Science and Technology, Trivandrum, Kerala, India and Academy of Scientific and Innovative Research, Ghaziabad, New Delhi, India

Esther T. Akinlabi
Pan African University for Life and Earth Sciences Institute, Ibadan, Nigeria

Mohammed Al-Maamori
University of Babylon-Iraq, Babylon, Iraq

Muthukaruppan Alagar
PSG Institute of Technology and Applied Research, Coimbatore, India

Mubarak Ali M
TKM College of Engineering, Kollam, Kerala, India

Adnan A. Alshukri
University Putra Malaysia, Serdang, Selangor, Malaysia and State Company for Rubber and Tyres Industry, Najaf, Iraq

Samira Alvani
Shahid Chamran University of Ahvaz, Ahvaz, Iran

Ramanathan Arunachalam
Sultan Qaboos University, Muscat, Oman

Sajid Asghar
Department of Pharmaceutics, Faculty of Pharmaceutical Sciences, Government College University Faisalabad, Faisalabad, Pakistan

Samuel A. Awe
Automotive Components Floby AB, Floby, Sweden

Faieza A. Aziz
University Putra Malaysia, Serdang, Selangor, Malaysia

Nuraini A. Aziz
University Putra Malaysia, Serdang, Selangor, Malaysia

Jaafar Al Hammad
King Fahd University of Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Mohamed A.A. Hanim
Universiti Putra Malaysia, Serdang, Selangor, Malaysia

Danish M. Baitab
University Putra Malaysia, Serdang, Selangor Darul Ehsan, Malaysia

Hamid Reza Bakhsheshi-Rad
Advanced Materials Research Center, Department of Materials Engineering, Najafabad Branch, Islamic Azad University, Najafabad, Iran and Faculty of Engineering, Universiti Teknologi Malaysia, Johor Bahru, Johor, Malaysia

Krishnasamy Balaji
PSG Institute of Technology and Applied Research, Coimbatore, India

Vincent A. Balogun
Edo University Iyamho, Iyamho, Edo State, Nigeria

Ajay Batish
Thapar Institute of Engineering and Technology, Patiala, India

Emin Bayraktar
Supmeca-Paris, School of Mechanical and Manufacturing Engineering, Saint-Ouen, France

P. Bedi
Guru Nanak Dev Engineering College, Ludhiana, India

Filippo Berto
Department of Mechanical and Industrial Engineering, Norwegian University of Science and Technology, Trondheim, Norway

Udaya Bhat K
Department of Metallurgical and Materials Engineering, National Institute of Technology Karnataka, Surathkal, Srinivasnagar, Karnataka, India

Devadas Bhat Panemangalore
Department of Metallurgical and Materials Engineering, National Institute of Technology Karnataka, Surathkal, Srinivasnagar, Karnataka, India

Kamaljit S. Boparai
MRS Punjab Technical University, Bathinda, India

Dermot Brabazon
I-Form, Advanced Manufacturing Research Centre, and Advanced Processing Technology Research Centre, School of Mechanical and Manufacturing Engineering, Dublin City University, Dublin, Ireland

Anisha Chaudhary
University of Delhi, New Delhi, India

Xizhang Chen
Wenzhou University, Wenzhou, China

Lebudi L. Colliueus
*Botswana International University of Science and
Technology, Palapye, Botswana*

Luis J. del Valle
*Chemical Engineering Department, Polytechnic
University of Catalonia, Barcelona, Spain*

Subramani Devaraju
*Vignan's Foundation for Science, Technology and
Research, Guntur, India*

Hajo Dieringa
Helmholtz-Zentrum Geesthacht, Geesthacht, Germany

Vishwesh Dikshit
Nanyang Technological University, Singapore

Mrityunjay Doddamani
*National Institute of Technology Karnataka, Surathkal,
Karnataka, India*

Ved P. Dubey
*Indian Institute of Technology (Indian School of Mines)
Dhanbad, Dhanbad, India*

Seid Reza Falsafi
*Gorgan University of Agricultural Sciences and Natural
Resources, Gorgan, Iran*

Leonardo I. Farfan-Cabrera
*Tecnologico de Monterrey, Escuela de Ingeniería y
Ciencias, Monterrey, México*

Nanang Fatchurrohman
Universiti Malaysia Pahang, Pekan, Pahang, Malaysia

Ahmad Fauzi Ismail
*Advanced Membrane Technology Research Center
(AMTEC), Universiti Teknologi Malaysia, Johor Bahru,
Johor, Malaysia*

Arjit Gadgil
Institute of Chemical Technology, Mumbai, India

Sarkis Gavras
Helmholtz-Zentrum Geesthacht, Geesthacht, Germany

Arsha Antony Geetha
*Council of Scientific & Industrial Research–National
Institute for Interdisciplinary Science and Technology,
Trivandrum, Kerala, India and Academy of Scientific
and Innovative Research, Ghaziabad, New Delhi, India*

N. Ghamarian
Universiti Putra Malaysia, Serdang, Selangor, Malaysia

Choon Fu Goh
Universiti Sains Malaysia, Penang, Malaysia

Manoj Gupta
National University of Singapore, Singapore

Vinay Gupta
University of Delhi, New Delhi, India

Soha Habibi
Iran University of Science and Technology, Tehran, Iran

R. Hamidi
*Technical University of Malaysia Melaka, Durian
Tunggal, Melaka, Malaysia*

Arumugam Hariharan
*PSG Institute of Technology and Applied Research,
Coimbatore, India*

Nurain Hashim
*University Putra Malaysia, Serdang, Selangor Darul
Ehsan, Malaysia*

Mohammed S.J. Hashmi
Dublin City University, Dublin, Ireland

Alaeddin B. Irez
*CentraleSupélec, University Paris-Saclay, Gif-sur-Yvette,
France and University Paris-Saclay, Gif-sur-Yvette,
France*

Sikiru O. Ismail
University of Hertfordshire, Hatfield, United Kingdom

Seid Mahdi. Jafari
*Gorgan University of Agricultural Sciences and Natural
Resources, Gorgan, Iran*

Ankit Jain
Indian Institute of Science, Bangalore, Karnataka, India

Subramanian Jayalakshmi
Wenzhou University, Wenzhou, China

Kamal K. Kar
*Department of Mechanical Engineering and Materials
Science Programme, Indian Institute of Technology
Kanpur, Kanpur, India*

Saeed Karbasi
*Biomaterials and Tissue Engineering Department, School
of Advanced Technologies in Medicine, Isfahan
University of Medical Sciences, Isfahan, Iran*

Jitendra K. Katiyar
*SRM Institute of Science and Technology, Chennai,
Tamil Nadu, India*

Daniel J. Kelly
*Trinity College Dublin, Dublin, Ireland; Advance
Materials and BioEngineering Research(AMBER) Centre
at Trinity College Dublin and the Royal College of
Surgeons in Ireland, Dublin, Ireland; and Centre for*

Research in Medical Devices (CURAM), National University of Ireland, Galway, Ireland

Syed H. Khalid
Department of Pharmaceutics, Faculty of Pharmaceutical Sciences, Government College University Faisalabad, Faisalabad, Pakistan

Adnan Khan
Qatar University, Doha, Qatar

Ikram U. Khan
Department of Pharmaceutics, Faculty of Pharmaceutical Sciences, Government College University Faisalabad, Faisalabad, Pakistan

Mahshid Kharaziha
Department of Materials Engineering, Isfahan University of Technology, Isfahan, Iran

Sergey Konovalov
Samara National Research University, Samara, Russia

Pradeep K. Krishnan
National University of Science and Technology, Muscat, Oman

Milli S. Kujur
Indian Institute of Technology (Indian School of Mines) Dhanbad, Dhanbad, India

Bhudolia S. Kumar
Nanyang Technological University, Singapore

Ranjiv Kumar
Guru Nanak Dev Engineering College, Ludhiana, India

Sudhir Kumar
Thapar Institute of Engineering and Technology, Patiala, India

Kai Bin Liew
University of Cyberjaya, Cyberjaya, Selangor, Malaysia

Peng Liu
Lanzhou University, Lanzhou, China

Huma Mahmood
Department of Pharmaceutics, Faculty of Pharmaceutical Sciences, Government College University Faisalabad, Faisalabad, Pakistan

Dayang L.A. Majid
University Putra Malaysia, Serdang, Selangor Darul Ehsan, Malaysia

Massoud Malaki
Isfahan University of Technology, Isfahan, Iran

Ashis Mallick
Indian Institute of Technology (Indian School of Mines) Dhanbad, Dhanbad, India

Vyasraj Manakari
National University of Singapore, Singapore

Ankita Mandal
Indian Institute of Technology, Delhi, India

Kaimanikal Madhurananthan Nair Sree Manu
Council of Scientific & Industrial Research, National Institute for Interdisciplinary Science and Technology, Trivandrum, Kerala, India and Brunel University, London, United Kingdom

Pradeep L. Menezes
University of Nevada, Reno, NV, United States

Shashank T. Mhaske
Institute of Chemical Technology, Mumbai, India

Ibrahim Miskioglu
Michigan Technological University ME-EM Department, Houghton, MI, United States

Elham Khademi Moghadam
Shahid Chamran University of Ahvaz, Ahvaz, Iran

Toraj Mohammadi
Iran University of Science and Technology, Tehran, Iran

Abdul Samad Mohammed
King Fahd University of Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Sanjay Mohan
Shri Mata Vaishno Devi University, Katra, Jammu, India

Michael G. Monaghan
Trinity College Dublin, Dublin, Ireland; Advance Materials and BioEngineering Research(AMBER) Centre at Trinity College Dublin and the Royal College of Surgeons in Ireland, Dublin, Ireland; and Centre for Research in Medical Devices (CURAM), National University of Ireland, Galway, Ireland

Subhash Nimanpure
Council of Scientific and Industrial Research, National Physical Laboratory, New Delhi, India

Bankole I. Oladapo
De Montfort University, Leicester, United Kingdom

Oluseyi P. Oladijo
Botswana International University of Science and Technology, Palapye, Botswana and University of Johannesburg, Johannesburg, Gauteng, South Africa

Akshay Padnuru Sripathy
National University of Singapore, Singapore

Farnoosh Pahlevanzadeh
Department of Materials Engineering, Isfahan University of Technology, Isfahan, Iran

Ballambettu Chandrasekhara Pai
*Council of Scientific & Industrial Research, National
Institute for Interdisciplinary Science and Technology,
Trivandrum, Kerala, India*

Sushanta K. Panigrahi
Indian Institute of Technology Madras, Chennai, India

Gururaj Parande
National University of Singapore, Singapore

P. Penjumras
*Universiti Putra Malaysia, Selangor, Malaysia and
Maejo University-Phrae Campus, Phrae, Thailand*

José Pérez-González
*Instituto Politécnico Nacional, Escuela Superior de Física
y Matemáticas, Ciudad de México, México*

Resego R. Phiri
*Botswana International University of Science and
Technology, Palapye, Botswana*

Rebaone E. Phuti
*Botswana International University of Science and
Technology, Palapye, Botswana*

Shiv K. Prajapati
*Ram-Eesh Institute of Vocational and Technical
Education, Greater Noida, Uttar Pradesh*

Sumit Pramanik
*Department of Mechanical Engineering, SRM Institute
of Science and Technology, Kancheepuram, Tamil Nadu,
India*

Somasundaram Prasadh
National University Centre for Oral Health, Singapore

Jordi Puiggalí
*Chemical Engineering Department, Polytechnic
University of Catalonia, Barcelona, Spain*

Gaofeng Quan
Southwest Jiaotong University, Chengdu, China

Gholamreza Masoudi Rad
Petroleum University of Technology, Ahvaz, Iran

Saba Rafique
*Department of Pharmaceutics, Faculty of Pharmaceutical
Sciences, Government College University, Faisalabad,
Faisalabad, Pakistan*

Ashok M. Raichur
Indian Institute of Science, Bangalore, Karnataka, India

Ankush Raina
*Shri Mata Vaishno Devi University, Katra, Jammu,
India*

V.K. Bupesh Raja
*Sathyabama Institute of Science and Technology,
Chennai, India*

Dipen K. Rajak
*Sandip Institute of Technology and Research Centre,
Nashik, Maharashtra, India*

Thazhivilai Ponnu Devaraj Rajan
*Council of Scientific & Industrial Research, National
Institute for Interdisciplinary Science and Technology,
Trivandrum, Kerala, India and Academy of Scientific
and Innovative Research, Ghaziabad, New Delhi, India*

Vaishnavi Ratheesh
National University Centre for Oral Health, Singapore

Mahmood Razzaghi
*Advanced Materials Research Center, Department of
Materials Engineering, Najafabad Branch, Islamic Azad
University, Najafabad, Iran*

Fizza A. Razzaq
*Department of Pharmaceutics, Faculty of Pharmaceutical
Sciences, Government College University Faisalabad,
Faisalabad, Pakistan*

Mattli M. Reddy
Qatar University, Doha, Qatar

Penchal Reddy Matli
National University of Singapore, Singapore

Lingbao Ren
Xi'an Jiaotong University, Xi'an, China

Hadis Rostamabadi
*Gorgan University of Agricultural Sciences and Natural
Resources, Gorgan, Iran*

A.M. Saad
*Technical University of Malaysia Melaka, Durian
Tunggal, Melaka, Malaysia*

Biranchi N. Sahoo
*Sardar Vallabhbhai National Institute of Technology,
Surat, Gujarat, India*

J.S. Saini
*Thapar Institute of Engineering and Technology, Patiala,
Punjab, India*

M.A. Salim
*Technical University of Malaysia Melaka, Durian
Tunggal, Melaka, Malaysia*

PREFACE

This is the first *Encyclopedia of Materials: Composites* published by Elsevier which presents a vast and widely encompassing content in the area of composite materials science and engineering. Composite materials have become even more important and ubiquitous over the recent decades due to the many advantages that they can provide over single monolithic materials. This includes improvements in the properties such as the physical, electrical, chemical, optical and magnetic properties which can be achieved by combining two or more materials.

The two main types of composites, Metal and Polymer matrix based, are presented in detail within Sections 1 and 2 respectively while Ceramic matrix composites are presented in Section 3. Smart composites which is an area that is growing fast with increasing industrial relevance is covered in Section 4. Assessing the properties of composite materials thereby enabling their application is a crucial aspect of composite materials development and usage. As such, Section 5 presents the testing methods used and property results from the testing of composite materials. The design of composite materials is covered in Section 6. The recyclability and sustainability of materials used in products is an ever more important topic. There are some challenges to achieve well the recyclability of composite constructs. The Encyclopedia presented two Sections covering this one (Section 7) covering nature based composites and another covering the life cycle analysis of composite materials (Section 8). In the last section of the Encyclopedia, Section 9 covers how to join composite materials together and with more conventional monolithic materials.

As an Encyclopedia, these sections were prepared to be the primary central source of background knowledge for undergraduate, postgraduate and researchers studying or working with composites. The audience of this work covers both academic and industrial researchers. In today's composite materials market, engineers, architects, and even policy makers, need reference literature where to find definitions, concepts and state-of-the-art knowledge. As such this Encyclopedia will be an invaluable reference for engineers, architects, scientists, and policy makers.

Each section contains articles written by world experts in their area. As well as providing the latest background information, the state of the art in the niche areas is presented in the individual articles. A particular concern in preparing these articles by the authors and Section editors was to make the content as accessible as possible to the reader. This is important given the multi-disciplinary nature of people working on the development and implementation of composite materials.

I take this opportunity to thank the 337 authors from across the world who have contributed the 171 articles to this Encyclopedia. It has been enjoyable to work with you are encouraging to see your expertise, interest and desire to help others from your contribution. With the many co-authored articles, there has been extensive collaboration which has resulted in a more informed and well-presented Encyclopedia content for the reader.

I am indebted also to the members of the Editorial team who have worked many long hours over the last couple of years to provide feedback and iterate on articles with the authors. The Editorial team have collectively many years of expertise working in their research areas. This team was formed via a variety networking events including conferences such as ESAFORM and Global Conference on Nanomaterial Forming (Manoj Gupta, Robertt Valente, Antonella Astarita), EU research projects and COST Actions (Fatima Zivic and Eva Maria Pellicer), and via other Dublin City University and sustainable engineering networking events (Mohamed El Mansori and Lorna Fitzsimons). I thank the Elsevier Major Reference Works team who supported in a professional manner the compiling of this work. In particular, I thank Laura Jackson, Sajana P K, and Ruth Rhodes for their direction and support throughout the preparation of this Encyclopedia.

Introduction to Metal Matrix Composite Materials: An Introduction

Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introducing Composites

Composite refers to a material that is an outcome of unification of two different class of materials ([Fig. 1](#)) ([Ceschini et al., 2016](#); [Gupta and Sharon, 2011](#)). To note that composites were used in making bricks in prehistoric times and more importantly by nature in providing functionality to both plants and animals including humans. The keen observations made by humans led to development of modern composites including MMCs.

Composites can traditionally be classified using two approaches:

- (1) Matrix based.
- (2) Reinforcement based.

Schematics of these approaches to classify composites are shown in [Figs. 2 and 3](#), respectively. For matrix-based classifications, there may be other matrices such as Carbon matrix but they are more specialized types and do not come under mainstream composites.

Based on reinforcements, the composites can be classified as (see [Fig. 4](#)):

- (1) Continuously reinforced composites.
- (2) Discontinuously reinforced composites.

Continuously reinforced composites display anisotropic properties while discontinuously reinforced composites exhibit isotropic properties.

Based on length scale of reinforcements, the composites can further be classified as shown in [Fig. 5](#). Each of these types of composites have their unique advantages and limitations and their selection for industrial applications depends largely on the properties requirements of the end applications.

Selection of metallic matrix for a composite is based on the combination of chemical, physical, thermal and mechanical properties and cost factor depending on the requirements of end applications ([Fig. 6](#)) ([Lloyd, 1994](#); [Ibrahim et al., 1991](#)).

Similarly, the selection of reinforcement is based on similar factors including the directionality of properties (isotropic or anisotropic) and compatibility with matrix (see [Fig. 7](#)).

Metal Matrix Composites – Matrix and Reinforcements

Metal matrix composites (MMCs) represent conscious unification of metallic matrix and at least one reinforcement. The reinforcement can be ([Ceschini et al., 2016](#); [Gupta and Sharon, 2011](#); [Lloyd, 1994](#); [Ibrahim et al., 1991](#); [Jayalakshmi and Gupta, 2015](#)):

- (1) Metallic.
- (2) Ceramic (oxides, carbides, nitrides, borides).
- (3) Intermetallic.
- (4) Carbon based (CNT, graphene, buckyball, graphene oxide).
- (5) Hollow (cenospheres, metal or ceramic based).
- (6) Hybrid (combination of above and combination of length scales).
- (7) Amorphous.
- (8) Multicomponent alloys.

Most commonly used metallic matrices include but not limited to the following:

- (1) Aluminum and its alloys.
- (2) Magnesium and its alloys.
- (3) Iron and its alloys.
- (4) Nickel and its alloys.
- (5) Copper and its alloys.
- (6) Tin and its alloys.
- (7) Titanium and its alloys.

Major factors that govern the properties of MMCs are based on: (a) Processing and (b) Constituents and (c) Microstructure (see [Fig. 8](#)) ([Lloyd, 1994](#); [Ibrahim et al., 1991](#)).

The capability of primary processing type on the microstructure and properties realization is expressed in [Fig. 9](#).

Fig. 1 Definition of composite.

Fig. 2 Matrix based classification of composites.

Fig. 3 Reinforcement based classification of composites.

Fig. 4 Continuously (left) and discontinuously (right) reinforced composites.

Fig. 5 Classification of composites based on length scale of reinforcement.

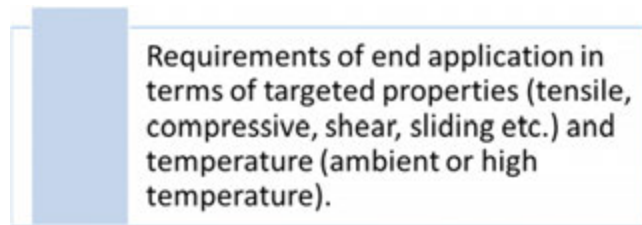

Fig. 6 Factors related to selection of matrix.

The major (not limited to) matrix and reinforcement related factors that govern the end properties of MMCs are shown in **Figs. 10** and **11**, respectively (Ceschini *et al.*, 2016; Gupta and Sharon, 2011; Lloyd, 1994; Ibrahim *et al.*, 1991).

Metal Matrix Composites – Processing

As indicated in **Fig. 9**, MMCs can primary processed using following economically viable routes (Lloyd, 1994; Ibrahim *et al.*, 1991):

- (1) Liquid phase methods.
- (2) Solid phase methods.
- (3) Two phase methods.

There are other methods that are being researched but those methods are still in the developmental stages for scalable and/or economical production. The liquid, solid and two-phase methods are listed in **Figs. 12–14**.

Among the liquid phase methods, the one including ultrasonic probes/transmitters are relatively new developments that have shown promising results.

Fig. 7 Factors controlling selection of reinforcement.

Fig. 8 Major factors governing the properties of MMCs.

Fig. 9 Processing type effects on microstructure and properties of MMCs.

Fig. 10 Matrix related factors governing the properties of MMCs.

Fig. 11 Reinforcement related factors governing the properties of MMCs.

Fig. 12 Most commonly used/researched methods to synthesize MMCs using liquid phase processing.

Among powder metallurgy methods, use of microwave sintering (Gupta and Leong, 2007), spark plasma sintering (Azarniya *et al.*, 2017), flake powder metallurgy (Xu *et al.*, 2017), molecular level mixing (Bakshi *et al.*, 2010) and friction stir processing (Eskandari *et al.*, 2016) are relatively new processes with significant potential.

Two phase methods probably were most exciting from metallurgical point of view, however, their utility in industrial processing is limited. Disintegrated melt deposition technique is the latest process in this category with potential of scalability at a very low equipment and infrastructural costs.

Fig. 13 Most commonly used/researched methods to synthesize MMCs using solid phase processing.

Fig. 14 Most commonly used/researched methods to synthesize MMCs using two phase processing.

Fig. 15 Most commonly used/researched secondary processing methods.

Fig. 16 Most commonly used/researched severe plastic deformation methods.

The selection of the process in each category depends largely on the:

- (1) Size of the part.
- (2) Geometry of the part.
- (3) Number of parts to be produced.
- (4) Microstructural characteristics expected in parts.
- (5) Level of properties expected from the end part.
- (6) Price tag of the final part.

Depending on the end application, at times the MMC billets are also secondary processed to further enhance their microstructural characteristics and properties. Common secondary processing techniques are indicated in [Fig. 15](#).

In more recent times, efforts are continuously made to significantly enhance the properties of MMCs using severe plastic deformation methods. Some of the promising methods severe plastic deformation processes used on bulk materials are listed in [Fig. 16](#).

Metal Matrix Composites – Properties

Like other structural materials, MMCs are used where certain enhanced functionalities from metallic materials is expected in end applications due to the more demanding nature of emerging end applications. Most commonly investigated properties where enhancement is expected include ([Ceschini et al., 2016](#); [Gupta and Sharon, 2011](#); [Lloyd, 1994](#); [Ibrahim et al., 1991](#)):

Fig. 17 Commonly used/researched joining methods for MMCs.

- (1) Coefficient of thermal expansion: For dimensional stability of parts.
- (2) Elastic modulus: For stiffness based designs.
- (3) Damping: For mitigating vibrations in structures that are prone to it.
- (4) Hardness: For erosion, wear and crack initiation resistance.
- (5) Strength: Tensile, compressive, flexural, torsional and high temperature.
- (6) Fatigue: Cyclic loading is common in many applications.
- (7) Creep: To enhance the working temperature limits.
- (8) Wear resistance: For sliding parts.
- (9) Erosion resistance: Such as in hydro-thermal power plants.

A detailed analysis of these properties can be found elsewhere in this encyclopedia and will not be discussed here.

Metal Matrix Composites – Joining

For industrial applications, joining of MMCs with MMCs or other metallic materials is required. Welding is one of the common practice for the same. Different joining methods that have evolved and used are indicated in [Fig. 17](#) (Ellis, 1996; Prater, 2011).

More recent development in joining of composites can be referred to in another article in this encyclopedia.

Metal Matrix Composites – Machining

Machining is an important operation before a part is assembled into a device. Machining is done on both the cast and wrought parts to different extents. Conventional machining processes such as turning, milling, drilling and wire cutting (EDM) are used for machining MMCs (Lane, 1992; Gururaja *et al.*, 2013). As traditional MMCs are reinforced with ceramic reinforcements which are typically harder than materials used for making conventional tools (e.g. tool steels), the wear or deterioration of tools increases faster affecting the surface characteristics of material that is machined. The problem is more severe when the micron and higher length scale ceramic reinforcements are used as they can be loaded to a higher extent. Similarly, reduction in particle diameter also assist in reducing tool wear and in that context, it is anticipated that nano-composites will perform better than microcomposites (Lane, 1992). Diamond coated tools in that respect display better machining performance.

While investigating a machining process, researchers typically focus and optimize on the following parameters (Gururaja *et al.*, 2013):

- (1) Workpiece material: Nature of metallic matrix and reinforcement associated variables.
- (2) Type of tool used: Polycrystalline diamond tools are most favored.

Fig. 18 Commonly used/researched surface protection methods for MMCs.

- (3) Use of lubricant.
- (4) Cutting speed.
- (5) Cutting depth.

It was emphasized by researchers that due to above mentioned factors and complexity of machining processes, detailed optimization of the parameters is important to ensure minimal tool wear and to realize desirable surface finish. Latest and detailed information on high performance machining of MMCs can be referred to in another article on machining in this encyclopedia in the Metal Matrix Composites section.

Metal Matrix Composites – Surface Protection

Surface protection of metallic surfaces is important and MMCs are no exception. The common purposes of providing surface protection include:

- (1) Corrosion protection: Both dry and wet.
- (2) Mechanical protection such as against scratches.
- (3) Erosion resistance.
- (4) Wear resistance.

Surface protection methods primarily include:

- (1) Painting: Layers of organic substances such as use of paints containing acrylic/vinyl resins.
- (2) Coating: Use of metallic layers or ceramic powders.
- (3) Surface treatment: Altering the surface characteristics using processes such as carburizing, laser hardening etc.

Fig. 19 Potential sectors for application of MMCs.

Various types under these categories are shown in [Fig. 18](#) and discussed in details elsewhere in this Encyclopedia.

Metal Matrix Composites – Applications

Metal matrix composites are actively been looked into many structural and non-structural applications and most prominent of them are indicated in [Fig. 19](#) ([Ceschini et al., 2016](#); [Gupta and Sharon, 2011](#); [Lloyd, 1994](#); [Ibrahim et al., 1991](#)). Main physical, thermal, mechanical and surface properties that are actively looked for these applications are:

- (1) Density: For light weighting.
- (2) Coefficient of thermal expansion: For dimensional stability.
- (3) Thermal conductivity: Heat management in transportation and electronic sectors.
- (4) Elastic modulus: For improving stiffness and deflection resistance.
- (5) Hardness: For erosion resistance such as in hydroelectric thermal plants.
- (6) Wear resistance: For sliding resistance such as in oil and gas and transportation sectors.

Most of the abovementioned properties can be easily tailored and realized using MMC technology. Besides investigators are looking into the possibility of using MMC technology in many other more specific applications which include and not restricted to the following:

- (1) Infrastructural applications.
- (2) Biomedical applications ([Gupta and Meenashisundaram, 2015](#)).
- (3) Recreational applications.
- (4) Home appliances such as CermeTi knives.
- (5) Nuclear applications for thermos-neutron shielding.

Challenges With MMC Technology

Active research in MMCs has almost spanned five decades and tremendous lessons are learnt on the fundamental principles governing their microstructure and properties. Researchers have convincingly established the efficacy of many formulations at lab scale and certain leading multinational companies have shown the capabilities to convert them into industrial products. However, the issue of scalability to synthesize MMCs using liquid metallurgy based high volume production routes with microstructural consistency is still a big issue for many countries for their widespread use. More involvement of industry is required to take these highly tailorable and property specific materials to the next level.

Fundamentals of Metal Matrix Composites

Sankaranarayanan Seetharaman and Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introduction

Metal matrix composites (MMCs) comprise of a continuous matrix of metallic alloys together with ceramic reinforcements, or metallic phases (Clyne and Withers, 1995). They offer a wide range of opportunities in various applications such as automobile, power train, aerospace, consumer electronics, packaging, and sports due to improved mechanical properties, wear resistance, creep resistance, damping characteristics, and reduced thermal expansion characteristics (Sijpkens and Vergouwen, 2004; Kainer, 2006; Barrett, 2017) (Fig. 1).

Fig. 2 Shows some of the commonly used matrix materials which include aluminum, copper, magnesium, titanium, nickel, steel whose properties are listed in Table 1. While MMCs based on aluminum, magnesium, and titanium alloys are the excellent candidates for lightweight structures in automotive, aerospace, and defense applications (Adebisi *et al.*, 2011; Jayalakshmi and Gupta, 2015), MMCs based on steel, nickel, and copper alloys are highly recommended for tooling, heavy industries, and electronic packaging, respectively.

In general, the reinforcement phases are hard and strong, and they are known to exhibit good thermal stability and Young's modulus. Hence, the inclusion of reinforcements can improve the performance of matrix material (Ashby, 2005; Callister and Rethwisch, 2007). Some of the commonly used reinforcements are shown in Figure and their properties are listed in Table 2. Based on the size and shape, reinforcements can be broadly classified into continuous and discontinuous reinforcement forms (Chawla and Chawla, 2004). The most common continuous reinforcement are the carbon or ceramic fibers. As these fibers are brittle and flaw sensitive, they are often provided protective coatings to avoid any unwanted chemical reactions and to improve the bonding/wetting characteristics. The fiber reinforcements are also known to exhibit size effects (i.e., the strength of these fibers decreases as the length increases), and they can be further classified into long or short fibers. Similarly, discontinuous reinforcement includes ceramic and metallic particulates in the size range from few nanometers to few hundred micrometers which are known to develop MMCs with isotropic properties (Chawla and Chawla, 2004; Kainer, 2006).

Classification of Metal Matrix Composites

Based on the type of reinforcement, MMCs are classified into (1) fiber reinforced MMCs, (2) particle reinforced MMCs, and (3) multi-layered laminates (Fig. 3). The fiber composites can be further classified as continuous and discontinuous fiber reinforced composites.

Fiber Reinforced MMCs

The fiber reinforced MMCs can be broadly classified into either (i) long, or (ii) short fiber reinforced metal matrix composites. While the long-fiber reinforced composites consists of a dispersed phase in the form of continuous fibers (length $> 100 \times$ diameter), the fiber lengths are often short ($< 100 \times$ diameter) in the case of short fiber reinforced MMCs.

TiC	Cub.	4.93	3140	29	7.4	–	320
TiN	Cub.	5.24	2950	29	9.4	–	600
WC	Hex	15.7	2800	110	5.2	9.5	690

Fig. 3 Classification of metal matrix composites.

Particulate Composites

Particulate composites consist of a matrix reinforced by particles that are dispersed randomly or with a well-defined orientation.

Nanocomposites

In particulate composites, when one of the dimensions of the particulate reinforcement is less than 100 nm, the resulting composite is referred to as nanocomposite. Recently, metal matrix composites containing nanoscale reinforcements are receiving stupendous attention as the low volume dispersion of hard and strong reinforcing phases in nano-length scale contributes significantly towards the strengthening of the matrix material. Unlike micron and sub-micron length scale reinforcement addition, the efficient dispersion of nanoscale reinforcement improves the strength of matrix material without adversely affecting the ductility (Goh *et al.*, 2006b; Casati and Vedani, 2014; Gupta and Wong, 2015).

Carbon nanotubes reinforced MMCs

The outstanding strength properties of carbon nanotubes (11–150 GPa) make them highly suitable for use as particulate reinforcements in various metal matrix composites (Popov, 2004; Goh *et al.*, 2006a; Esawi and Farag, 2007; Bakshi *et al.*, 2010; Neubauer *et al.*, 2010; Bhat *et al.*, 2011; Casati and Vedani, 2014). Although several publications report the exceptional strengthening promise of multiwalled CNT, defect free processing of CNT reinforced MMCs is challenging. Some of the recent research works also explored the effects of nanoscale graphene platelets (Saboori *et al.*, 2018) and other advanced engineering materials such as metallic glass (Jayalakshmi *et al.*, 2018) and shape memory alloys (Ferguson *et al.*, 2014; Rohatgi, 2014) as discontinuous reinforcement.

Laminate Composites

Composite laminates consist of multiple layers of sheet laminates made of the matrix and reinforcement materials stacked and cemented in a specific pattern in order to achieve the desired strength. Based on the stacking sequence, the composite laminates are classified into angle and cross-ply laminates which can be either symmetric, antisymmetric, or balanced. Fig. 4 shows the construction of a lightweight laminated composite (0.16 kg) developed to replace the aluminum heat sink (0.29 kg) of printed circuit boards.

Processing of Metal Matrix Composites

A variety of methods can be employed in the fabrication of metal matrix composites and they can be broadly grouped under either liquid or solid-state processing methods. Similarly, based on the nature of reinforcement addition, the processing methods can be either ex-situ or in-situ processing.

Fig. 4 Lightweight laminated composite heat sink developed for printed circuit boards. Redrawn from Holz, J.M., Niemeyer, L., Puckett, D., 2000. Composite-Material Heat Sink for Printed-Circuit Boards, Technical Support Package. GSC-14142. Goddard Space Flight Center. Available at: <https://www.techbriefs.com/component/content/article/tb/techbriefs/materials/6720>.

Liquid State Processing

Liquid state processing generally involves the preparation of a composite slurry through the dispersion of reinforcement materials into a molten matrix which is then followed by the solidification into required shape. Here, the reinforcement dispersion can be performed using multiple ways such as: (1) melt infiltration, (2) stir casting or compo-casting, and (3) melt deposition.

Melt infiltration

Melt infiltration involves either spontaneous or forced infiltration of a liquid metal alloy into a porous preform containing fibers/whiskers reinforcements upto 70 vol% (Kainer, 2006). The spontaneous infiltration is also known as pressure less infiltration in which no external pressure or force is used to process MMCs based on Al-Si, Al-Mg, and Al-Zn alloys with better flowability. However, the poor wettability between the matrix and the reinforcing phase slows down the fabrication process resulting in undesirable reaction products at the interface. Several studies have reported an improvement in the wettability through activators or processing in nitrogen atmosphere. In forced infiltration process, the infiltration of molten metal into the porous reinforcement is achieved through the application of external pressure or by using mechanical force as shown below to overcome the issues associated with poor wetting and adhesion characteristics.

Pressure die infiltration:

In pressure die infiltration, the molten composite slurry is force injected into the mold using an injection barrel (Cook and Werner, 1991; Altinkok *et al.*, 2003). The key advantages of this methods are its low cost and the high precision capability (Figs. 5 and 6).

Gas pressure infiltration:

In this process, the reinforcement preforms are infiltrated using pressurized inert gas in which the gas pressure can be applied in two ways: (1) application of gas pressure to the melt surface after dipping the preform into the melt for infiltration, (2) the applied gas first presses the molten bath into the preform and then infiltrates the bath (Daoud, 2004). Generally, the gas pressure is applied in combination with vacuum at the other end of preform to avoid air entrapment to help easy penetration at lower pressures. Since reaction times are relatively short, fibers are subjected to less damage (compared to other processes) and the reactive materials can be processed without difficulty. Also, this method can be used for large-scale production of the composite materials.

Ultrasonic infiltration:

In this process, the pressure waves generated by ultrasonic vibrations assists in the acoustic cavitation and the collapse of bubbles originating close to the molten metal helps in the penetration of molten metal into the reinforcement preform (Matsunaga *et al.*, 2007). Fig. 7 shows the ultrasonic infiltration experimental setup used to fabricated carbon fiber reinforced Al composite wires.

Fabrication of continuous carbon fiber-reinforced aluminum-magnesium alloy composite wires using ultrasonic infiltration method. Composites Part A: Applied Science and Manufacturing. 38 (8), 1902-1911. doi:[10.1016/j.compositesa.2007.03.007](https://doi.org/10.1016/j.compositesa.2007.03.007).

Fig. 8 Centrifugal infiltration setup and principle. From Sánchez, M., Rams, J., Ureña, A., 2010. Fabrication of aluminium composites reinforced with carbon fibres by a centrifugal infiltration process. *Composites Part A: Applied Science and Manufacturing*. 41 (11), 1605-1611. doi:[10.1016/j.compositesa.2010.07.014](https://doi.org/10.1016/j.compositesa.2010.07.014). Sánchez-Martínez, A., *et al.*, 2016. Main process parameters for manufacturing open-cell Zn-22Al-2Cu foams by the centrifugal infiltration route and mechanical properties. *Materials and Design*. 108, 494-500. doi:[10.1016/j.matdes.2016.07.032](https://doi.org/10.1016/j.matdes.2016.07.032).

Centrifugal infiltration:

In this process, the reinforcement is positioned inside a mold with long runners filled with molten metal which infiltrates the preform under large rotational velocities or centrifugal forces which is given by:

$$P_c = \frac{1}{2} \rho \omega^2 (L^2) \quad (1)$$

where, P_c = pressure generated at the preform top surface during the rotation in centrifugal casting, ρ = density of the molten metal, $\omega = 2\pi\Omega/60$ where Ω is rotational speed (rpm), L = molten metal level from the rotational axis (Sánchez *et al.*, 2010; Sánchez-Martínez *et al.*, 2016) (Fig. 8)

Lorentz force infiltration:

It is an infiltration technique in which a high frequency electromagnetic pulse is used to immerse the reinforcement into the molten metal and the interaction of magnetic pulse with eddy current generates Lorentz force to force the liquid metal to enter in reinforcement phase at a very high speed (Andrews and Mortensen, 1991) (Fig. 9).

Squeeze casting:

Squeeze casting infiltration process is one of the widely used fabrication techniques for producing net shape MMCs with control over shapes, chemistry, volume fraction and distribution of reinforcement (Uozumi *et al.*, 2008). In squeeze casting, the molten metal is forced into the preform and a pressure is applied until the solidification is complete. This method can be applied for both the fibers and particles reinforced composites as the prefabricated fiber or particle preforms can be melt infiltrated and solidified under pressure. To avoid damage to the preforms, the melt is first pressed into the preform at low pressure and then the pressure is increased for solidification. Since the melt solidifies under very high pressure, the squeeze cast composites are free from the common casting defects such as porosity and shrinkage cavities. As the duration of the infiltration is relatively short, the squeeze casting method can be applied for reactive materials like magnesium (Jayalakshmi *et al.*, 2006) (Fig. 10).

Based on the mode of pressure application, squeeze casting can be classified into direct and indirect squeeze casting. In direct squeeze casting method, pressure for the infiltration of preforms is applied directly to the melt. However, in indirect squeeze casting, the melt is pressed into the preform through a gate system. Although the tooling is relatively simple for direct squeeze casting, the absence of gate system necessitates accurate determination of the melt volume. Another disadvantage is the presence of oxide residue in the composite which are normally restricted by the gate in the indirect squeeze casting.

Fig. 10 Squeeze casting. Redrawn from Garg, P., *et al.*, 2019. Advance research progresses in aluminium matrixcomposites: Manufacturing & applications. Journal of Materials Research and Technology. 8 (5), 4924–4939. doi:10.1016/j.jmrt.2019.06.028.

Stir casting

Stir casting or compo-casting is the most common and cost-effective method of producing composite materials (Kainer, 2006; Tzamtzis *et al.*, 2009). In this method, the reinforcement phase (fiber or particles) is mixed with the molten matrix metal by means of mechanical or ultrasonic stirring. The molten composite slurry is then cast by conventional casting methods. The properties of the MMCs produced using stir casting methods will depend on the processing parameters such as temperature of melt, stirring speed, stirring duration, geometry of the stirrer and size of crucible which will affect the distribution of the reinforcements in the matrix. The dispersed phases are also often coated with proper wetting agents to achieve better interfacial bonding with the matrix material and to avoid any unwanted reaction and the dissolution of reinforcement at high temperatures. In case of particulate reinforcement, careful attention must be paid to the dispersion of the particles as they tend to form agglomerates. In general, the

Fig. 11 Schematic of (a) mechanical stir casting and (b) ultrasonic stir casting.

proper selection of processing parameters such as melt temperature, stirring speed, duration, and stirrer geometry, etc., allows the effective dispersion of particles (in the size range 5–100 μm) up to 30% by volume (Fig. 11).

Melt deposition

There are several deposition techniques available to produce metal matrix composites. While deposition methods like immersion and electroplating, chemical vapor deposition (CVD), physical vapor deposition (PVD) are only used for fiber reinforced MMCs, the spray and disintegrated melt deposition methods can be used for both the particle reinforced metal matrix composites (Harrigan, 1998).

Immersion plating:

This method is applicable for continuous fiber reinforcement which are passed through baths of molten metal, slurry, sol, or organometallic precursors.

Electroplating or electrodeposition:

In this method, the matrix metal coating is produced from a solution containing the ion of the desired material in the presence of an electric current. As this process is carried out at moderate temperatures, this method offers less/no damage to the reinforcement fibers. However, processing defects such as poor bonding and porosity are common for MMCs produced using this method. Also, only limited alloy matrices can be processed using this method.

Chemical vapor deposition:

It involves chemical reaction or decomposition of a vaporized component on to the substrate to form a coating. Using this method, amorphous and crystalline (single and polycrystals) coatings of oxide, carbide, nitride, or pure metals can be made. When this method is used to deposit the matrix material on the reinforced preforms, it is called chemical vapor infiltration.

Physical vapor deposition:

This method is highly suitable for producing fiber reinforced metal matrix composites in which the vapors of matrix metal were condensed to create coatings on the reinforcement fibers. The coated fibers are then consolidated by hot pressing or hot isostatic pressing. Based on the vapor generation techniques, the PVD processes can be classified into: (1) evaporation based, (2) sputtering, and (3) ion-plating. While the evaporation PVD methods include techniques based on electron beam/arc evaporation, radiation heating, laser ablation and resistive heating, the sputtering techniques involve vaporization of the coating material from an ionized argon gas molecule via momentum transfer. Similarly, ion plating involves passing the vaporized component through an argon gas glow discharge around the substrate which ionizes and subsequently deposit the vapor onto the substrate.

The primary advantage of PVD is the versatility in the compositions of the coating produced and the superior bonding with the substrate. In addition, there are no chemical reaction by products in these methods. However, the PVD methods are relatively complex and expensive.

Spray deposition:

In spray deposition, reinforcements in the form of particles/whiskers are injected into the spray of molten metal, creating a deposition layer on the substrate (Wood, 1997). The depositions are then densified by suitable post-processing techniques. Similarly, for continuous fiber reinforcements, the molten matrix metal is sprayed onto the fibers with preferred orientation. In this method, fiber alignment can be easily controlled and a relatively faster solidification rates can be achieved.

Fig. 12 Spray deposition. Redrawn from Garg, P., *et al.*, 2019. Advance research progresses in aluminium matrixcomposites: Manufacturing & applications. Journal of Materials Research and Technology. 8 (5), 4924–4939. doi:10.1016/j.jmrt.2019.06.028.

It is a promising method for producing particle reinforced MMCs. It involves spray techniques which are used to develop monolithic alloys. Fig. 12 shows an example of the spray forming process in which a spray gun is used to atomize the molten matrix metal into which the reinforcement particles are injected. The resulting metal matrix composite (about 97% dense) is then subjected to scalping, consolidation, and secondary finishing processes to produce wrought composites. To facilitate the efficient transfer of particle reinforcement, an optimum particle size and shape must be maintained.

Disintegrated melt deposition:

Disintegrated melt deposition (DMD) is a unique liquid processing technique which combines the advantages of stir casting and spray processing methods (Gupta *et al.*, 1995) (Fig 13). It involves the vortex mixing of reinforcements and the deposition of molten slurry onto a metallic substrate after disintegration by jets of inert gases. Unlike spray deposition, DMD employs lower impinging velocity to achieve a bulk composite. Hence, it offers the features of (1) fine grain structure and low segregation of reinforcements of spray process and (2) simplicity and cost effectiveness of conventional stir cast foundry process.

Solid State Processing

Some of the widely used solid-state processing methods include (1) powder mixing, (2) mechanical alloying, (3) diffusion bonding, and (4) deformation processing.

Powder consolidation

In this method, the required amounts of matrix alloy and reinforcement powders are mixed to prepare a composite blend which is then cold or hot compacted into a billet. The prepared green billet is then canned, degassed and sintered at temperature closer to the solidus temperature of the matrix alloy (Sankaranarayanan and Gupta, 2015) (Fig. 14).

While this method can be effectively used for particle reinforced aluminum or magnesium composites, cold-pressing and sintering are not preferred in case of long fiber reinforcement which are often damaged under the high pressure. Hence, for long continuous fibers, the fiber tows are first infiltrated by dry matrix powder which is then followed by hot isostatic pressing (Gupta and Sharon, 2010).

Mechanical alloying

Mechanical alloying involves repeated cold welding, fracturing, and re-welding of powder particles in a high energy ball mill (Suryanarayana, 2001). In this process, the frictional heat developed at the particle interface results in the local melting and consolidation of powder particles. The composite powder mixture obtained from ball-milling is then densified using cold or hot-pressing techniques (Sankaranarayanan and Gupta, 2015) (Fig. 15).

Due to the nature of high dislocation densities generated in this method and the homogenous distribution of reinforcing constituents, this method can be effectively applied to develop a range of equilibrium/non-equilibrium alloys and composites with excellent set of properties.

Post-processing (or) sintering of powder compact

Cold compacted billets from the powder mixing and mechanical alloying methods are often heat treated or sintered for better densification and strengthening. It involves heating of the green compact to a temperature closer to the solidus line of the matrix

Fig. 13 Disintegrated melt deposition. Reproduced from Gupta, M., Wong, W.L.E., 2015. Magnesium-based nanocomposites: Lightweight materials of the future. *Materials Characterization*.105, 30-46. doi:[10.1016/j.matchar.2015.04.015](https://doi.org/10.1016/j.matchar.2015.04.015).

Fig. 14 Powder consolidation.

alloy for a certain period in order to allow atomic diffusion and inter-particle bonding (Padmavathi *et al.*, 2011; Slotwinski *et al.*, 2014). In most cases, the sintering of green powder compact also facilitates the microstructural recrystallization for strengthening alongside densification and removal of residual lubricant (Fig. 16).

Fig. 15 Schematic showing mechanical alloying.

Fig. 16 Stages in sintering: Stage I: Particle bonding in green compact, Stage II: Growth of contact points into 'necks' and Stage III: final microstructure showing grains and pores.

Microwave assisted rapid sintering

Microwave sintering has recently emerged as an energy efficient technique to consolidate powder materials (Wong and Gupta, 2007; Gupta and Eugene, 2011; Padmavathi *et al.*, 2011). While the microwave processing has been largely limited to ceramic materials in the past, recent literatures confirm that the metallic materials can also be densified using the microwaves. However, it should be noted that the microwave heating is fundamentally different compared to conventional heating. In conventional heating, the transfer of heat from the surface to the interior of material takes place by conduction, convection and radiation. However, microwave heating involves the self-heating of material core due to dielectric and magnetic losses resulting from the interaction between the electric and magnetic fields (Fig. 17). Since microwaves exhibit an inverse temperature distribution, the heating by microwaves happens rapidly from the core to the surface and cause a substantial reduction in the processing time by more than 80%. Hybrid microwave sintering utilizing susceptors in recent year has emerged to minimize temperature and microstructural variations across the thickness of samples.

Diffusion bonding

Diffusion bonding is a solid-state technique used to process a wide variety of fiber reinforced MMCs. It involves the interdiffusion of atoms at the mating surface between the matrix and reinforcement to cause chemical/mechanical bonding under the influence of temperature and pressure (Fig. 18). Although the fiber orientation and volume fraction can be effectively controlled, the processing time and cost are relatively high thus limiting its extended application.

Deformation processing

Fabrication methods based on mechanical deformation are highly applicable for metal-metal or layered metal composites. Fig. 19 illustrates the methodology of roll bonding process used to produce sheet metal composite laminates. Here, a two-phase alloy

Fig. 17 Schematic of microwave sintering and heat transfer principle. Modified from Penchal Reddy, M., *et al.*, 2016. Microwave rapid sintering of al-metal matrix composites: A review on the effect of reinforcements, microstructure and mechanical properties. Metals. doi:10.3390/met6070143.

Fig. 18 Schematic showing diffusion bonding process. Redrawn from Garg, P., *et al.*, 2019. Advance research progresses in aluminium matrixcomposites: Manufacturing & applications. Journal of Materials Research and Technology. 8 (5), 4924–4939. doi:10.1016/j.jmrt.2019.06.028.

material is subjected to mechanical deformation causing the minor phase to elongate and become fibrous within the matrix (major phase). However, it should be noted that this method is limited to ductile two-phase materials in which the two phases exhibit similar flow stresses pattern for co-deformation. Further, the deformation processed materials also require post-processing heat treatments to reduce mechanical anisotropy.

In-Situ Processes

In-situ methods include processes based on liquid–gas, liquid–solid, liquid–liquid, and mixed salt reactions in which the chemical reaction between reacting constituents leads to in-situ formation of reinforcement (Harrigan, 1998; Thein *et al.*, 2009; Ghosh *et al.*, 2010;

Fig. 19 Roll bonding process for making a laminated MMC. Reproduced from Khaledi, K., *et al.*, 2018. Modeling of joining by plastic deformation using a bonding interface finite element. *International Journal of Solids and Structures*. doi:10.1016/j.ijsolstr.2018.10.014.

Fig. 20 Self-propagating high temperature synthesis of MMCs. Redrawn from Garg, P., *et al.*, 2019. Advance research progresses in aluminium matrixcomposites: Manufacturing & applications. *Journal of Materials Research and Technology*. 8 (5), 4924–4939. doi:10.1016/j.jmrt.2019.06.028.

Jayalakshmi *et al.*, 2013). Hence, a good understanding of reaction kinetics and thermodynamics is essential in order to obtain the desirable end-products. Generally, the in-situ developed composites exhibit very fine and well dispersed reinforcement phases which are stable and free from surface contaminants and has a coherent interface assisting in stronger bond between the reinforcement and the matrix material.

One of the well-known examples of in-situ methods is the unidirectional solidification of eutectic alloy resulting in the formation and distribution of fibers like phases in the matrix alloy (Livingston, 1974). Sometimes, it is also referred to as self-propagating high temperature synthesis (SHS) when the reinforcing phases are produced by exothermic reaction between the matrix constituents (Subrahmanyam and Vijayakumar, 1992; Mossino, 2004; Xiao *et al.*, 2004) (Fig. 20). In these methods, the characteristics of the reinforcing phases, especially the interfacial compatibility are controlled by the solidification rate which is generally limited to $\sim 1\text{--}5$ cm/h to maintain the temperature gradient for a stable growth front.

Additive Manufacturing

Laser-based additive manufacturing techniques such as selective laser melting and laser deposition were also used to fabricate metal matrix composites based on Al, Ti, and Ni based matrix materials (Gu *et al.*, 2012; Manfredi *et al.*, 2014; Pouzet *et al.*, 2016;

Fig. 21 Schematic of selective laser melting and laser deposition methods. Courtesy Benedyk, J.C., 2018. Additive manufacturing of aluminum alloys: Augmenting or competing with traditional manufacturing? *Light Metal Age*.

Aboulkhair *et al.*, 2019; Behera *et al.*, 2019). These methods involved a high energy laser source to melt and deposit the powder raw materials in a layer-by-layer fashion (Fig. 21). In most cases, the reinforcement phases are often developed in-situ due to the chemical reaction between the powder raw materials (Banerjee *et al.*, 2005; Attar *et al.*, 2014a). On the other hand, the laser processing of ex-situ prepared composite powder mixture was also investigated and it was found that the composite powder preparation plays an important role in determining the end properties of the bulk composite (AlMangour *et al.*, 2016, 2017a,b; Famodimu, 2016).

Properties of MMCs

The end properties of composite materials are controlled by many variables including reinforcement form, volume fraction, geometry, distribution, matrix/reinforcement interface, void content, and manufacturing process. The presence, amount, and distribution of reinforcement influence the dislocation behavior and hence the physical and mechanical properties of the composites. In addition to physical and mechanical properties, the reinforcement also influences other material properties such as the wear resistance and damping capacity. The mechanical properties of MMCs are not only affected by the properties of matrix and reinforcing materials, but also by the interfacial characteristics and it is well established that the weak bonding between them generally worsen the properties of MMCs. The following section will provide an overview of the properties of metal matrix composites.

Volume and Weight Fractions

Based on the rule of mixtures, the properties of a composite material are the volume weighed average of the phases (matrix and dispersed phase) properties. Hence, to estimate the mechanical properties of a composite material, it is important to know the relative proportions of matrix and reinforcement. The proportion can be expressed in terms of volume fraction of weight (or mass) fraction. Weight fractions are commonly used as it is easy to weigh the relative proportions of matrix and reinforcement using an analytical balance. The volume fraction is used in the computation of the properties of the composite, therefore knowing the conversion between weight and volume fraction is essential.

The relationships between the volume fractions and weight fractions can be expressed as:

$$W_m = \frac{\rho_m}{\rho_c} V_m \text{ and } W_R = \frac{\rho_r}{\rho_c} V_r \quad (2)$$

where,

W_m and W_r → weight fraction of matrix and reinforcement materials, respectively,
 V_m and V_r → volume fractions of matrix and reinforcement materials, respectively

ρ_m , ρ_r and $\rho_c \rightarrow$ densities of matrix, reinforcement and the composite, respectively.

Density

The density of metal matrix composite can be calculated using the rule of mixtures as follows:

$$\rho_c = \rho_m V_m + \rho_r V_r \text{ (or) } \rho_c = \frac{1}{\frac{V_m}{\rho_m} + \frac{V_r}{\rho_r}} \quad (3)$$

Coefficient of Thermal Expansion

Based on the rule of the rule of mixtures (Dieter and Bacon, 1988), the thermal expansion coefficient of composite material can be computed as follows:

$$\alpha_c = \alpha_m V_m + \alpha_r V_r \quad (4)$$

where α_c , α_m and α_r refers to the thermal expansion coefficients of the composite, matrix and reinforcement materials, respectively.

For continuous fiber reinforced metal matrix composites, the thermal expansion coefficients along the longitudinal and transverse directions can be calculated as follows:

CTE in longitudinal direction (along the fibers),

$$\alpha_{cl} = \frac{\alpha_m E_m V_m + \alpha_r E_r V_r}{E_m V_m + E_r V_r} \quad (5)$$

CTE in transverse direction (perpendicular to the fibers),

$$\alpha_{ct} = (1 + V_m) \alpha_m + \alpha_r V_r \quad (6)$$

where E_m , E_r are the elastic moduli of the matrix and the fiber reinforcement respectively and v_m refers to the poisson's ratio of the matrix.

Similarly, for particle reinforced MMCs, the coefficient of thermal expansion can also be calculated based on the Turner model (Elomari *et al.*, 1998) as below:

$$\alpha_c = \frac{(\alpha_m V_m K_m + \alpha_r V_r K_r)}{(V_m K_m + V_r K_r)} \quad (7)$$

where K_m and K_r is the bulk modulus of matrix and reinforcement, respectively.

Modulus of Elasticity

The elastic behavior of a composite depends on the type and volume fraction of the reinforcement and it generally improves with the addition of the reinforcement (Dieter and Bacon, 1988):

$$E_C = E_m V_m + E_r V_r \quad (8)$$

Along the transverse direction,

$$E_{ct} = \frac{1}{\left(\frac{V_m}{E_m} + \frac{V_r}{E_r}\right)} \quad (9)$$

For discontinuous fibers and particle (aspect ratio: s) reinforced composites, the elastic modulus can be calculated as follows:

$$E_c = \frac{E_m(1 + 2sqV_r)}{1 - qV_r} \text{ when } q = \frac{\left(\frac{E_r}{E_m} - 1\right)}{\left(\frac{E_r}{E_m} + 2s\right)} \quad (10)$$

Tensile Strength

Metal matrix composites exhibit better strength when compared to their unreinforced matrix metals and the same can be calculated as follows:

$$\sigma_c = \sigma_m + \sqrt{\sum \Delta \sigma_i^2} \quad (11)$$

where σ_c and σ_m refers to the strength of the composite and the matrix respectively and $\Delta \sigma$ refers to the strengthening contribution from various strengthening mechanism as described below:

Load transfer

The transfer of load from relatively soft and compliant matrix material to the hard and strong reinforcement actively contributes towards the strengthening of matrix as proposed in the original and modified shear lag theories (Fukuda and Chou, 1981; Clyne, 1989) as follows:

$$\Delta\sigma_{LT} = V_r \sigma_m \frac{(L+t)AL}{4L} \quad (11a)$$

where σ_m , L and t refers to the matrix yield strength, and reinforcement dimensions in terms of length and thickness, respectively. Hence, for equiaxed particle reinforcements, the strength contribution from load transfer may be expressed simply as $\Delta\sigma_{LT} = 0.5V_r \sigma_m$

Strengthening due to CTE and EM mismatch

The dislocation density in a composite matrix is generally higher due to the thermal stresses caused by the mismatch in CTE ($\Delta\alpha_{CTE}$) and modulus ($\Delta\sigma_{EM}$) values between the matrix and the reinforcement materials (Dieter and Bacon, 1988; Callister and Rethwisch, 2007).

$$\Delta\sigma_{CTE} = \frac{A\Delta\alpha\Delta TV_r}{b d v_m} \quad (11b)$$

$$\Delta\sigma_{EM} = \frac{6V_r}{\pi d} \quad (11c)$$

where A is a geometric constant, $\Delta\alpha$ is the CTE mismatch, ΔT is the temperature difference, b is Burgers vector and d is reinforcement size.

Thermal residual stresses

The strengthening contribution from residual stress due to thermal cycling at high temperatures can be calculated using the following relation (Chawla and Chawla, 2004):

$$\Delta\sigma_{Ts} = \frac{E_r E_m}{E_r V_r + E_m V_m} V_r \Delta\alpha \Delta T \quad (11d)$$

Orowan strengthening

Orowan mechanism applies to dispersion strengthened materials in which the dislocation motion is restricted by presence of reinforcements in the form of fibers or particles which can be expressed as (Dieter and Bacon, 1988; Callister and Rethwisch, 2007):

$$\Delta\sigma_{OR} = \frac{0.13bG}{d_r \left[\left(\frac{1}{2V_r} \right)^{1/3} - 1 \right]} \ln \left(\frac{d}{2b} \right) \quad (11e)$$

where G is the matrix shear modulus.

Grain refinement strengthening

In polycrystalline metals, grain boundaries play an important role in strengthening as they impede the dislocation motion at low temperatures to increase the stress required for continuing the deformation process (Dieter and Bacon, 1988; Callister and Rethwisch, 2007). As the matrix grain size of MMCs is usually smaller than that of the unreinforced counterparts, the greater grain boundary area prevents the dislocations from moving in a continuous slip plane leading to an increase in the yield strength. The Hall–Petch equation relates the yield strength of the material with the average grain size (d) as follows:

$$\Delta\sigma_{HP} = \frac{K_y}{\sqrt{d}} \quad (11f)$$

where K_y is the strengthening coefficient which is a characteristic constant of each material.

In a recent work, Zhang and Chen proposed the following simplified model considering the strengthening mechanisms such as Orowan strengthening mechanism, CTE mismatch effect, and load-bearing effect as follows:

$$\sigma_c = (1 + 0.5V_r) \left(\sigma_m + A + B + \frac{AB}{\sigma_m} \right) \quad (12)$$

$$A = 1.25G_m b \sqrt{\frac{12\Delta\alpha\Delta TV_r}{b d V_m}} \quad (12a)$$

$$B = \frac{0.13G_m b}{d^{1/3} \sqrt{\frac{1}{2}V_r - 1}} \ln \frac{d}{2b} \quad (12b)$$

Application of MMCs

Metal matrix composites are used in a range of applications ranging from aerospace, space, automobile, cutting tools, power transmission, consumer electronics, defense, and sports (Clyne and Withers, 1995; Kainer, 2006).

The enhanced stiffness and strength of the MMCs make them highly suitable for applications in military and commercial aircrafts. For example, the aluminum access doors in the F-16 aircraft have been replaced with SiC particle reinforced MMCs for fatigue life improvement (Hunt, 2001). Similarly, the SiC monofibre reinforced Ti-composites are used to replace the heavier IN718 and stainless-steel components of the F119 engine in F-16 (Warrier, 1995; Doorbar *et al.*, 2009). Some other examples include ~20% lighter airframe of Boeing 787 made of largely carbon fiber composites and the fan-exit guide vane of a Pratt & Whitney engine on a Boeing 777 (Haghshenas, 2016). Recently, structural components for tank armours are also made using BN reinforced steel composites.

Transportation sector has been the prime consumer of MMCs and the applications in this field include drive shafts, engine and brake components. For example, modern sport cars built by Porsche use rotor components made of carbon fiber composites with better specific heat and thermal conductivity (Chawla and Chawla, 2006; Macke *et al.*, 2012). Similarly, Al-Si matrix composites containing Al₂O₃ and carbon with improved wear resistance and ~50% weight savings are used in the cylinder liner of Honda Prelude (Chawla and Chawla, 2006; Nicolais *et al.*, 2012; Macke *et al.*, 2012). Other automotive applications of MMC include piston rings made of short Saffil fiber reinforced Al composites in Toyota car models, connecting rods and drive shafts made of SiC/B₄C particle-reinforced aluminum-matrix composites for structural lightweighting of racing cars, and Duralcan supplied brake rotors of German high-speed train made of SiC particles reinforced AlSi₇Mg composite with ~43% weight savings (Cayron, 2001; Chawla and Chawla, 2006; Nicolais *et al.*, 2012; Macke *et al.*, 2012). Similarly, the brake calipers and pushrods supplied by 3M also offer upto 50% weight saving potential (Hunt Warren and Miracle, 2001).

Another common example of MMCs is the lightweight bicycle frame made using aluminium/titanium matrix composites and carbon fibers. Some other sporting applications include fishing rods, bicycle frames, golf club heads, and tennis/squash rackets (Koczak *et al.*, 1993). MMCs reinforced with carbide and nitride particles are also widely used as cutting tool materials (Ozben *et al.*, 2008).

In electronics applications, MMCs are used in the new generation advanced integrated circuits to overcome heat dissipation and thermal fatigue concerns. Dymalloy, a metal matrix composite containing diamond particles in copper-silver alloy matrix with very high thermal conductivity and adjustable thermal expansion coefficients are used as substrates for high power, high density multi-chip modules in microelectronics (Davidson *et al.*, 1995; Kerns *et al.*, 1996). Similarly, continuous Al₂O₃ fiber reinforced Al MMCs with adjustable CTE are used as electrical conductors for power transmission (Huda *et al.*, 1995).

Challenges and Recommendations

In this article, the fundamentals of metal matrix composites are discussed in terms of their classification, processing, and properties. Their applications in key engineering sectors such as automobile, aerospace, and electronics are also briefly reviewed. As of now, the research works on MMCs largely focussed on lightweight metals such as Al, Mg, Ti for automotive and aerospace applications. However, materials like copper, tin, and iron also offer exceptional promise in electronics and tooling applications.

The lightweight MMCs with desirable properties such as high specific modulus, better thermal stability, and wear/abrasion resistance have emerged as the front runner for weight critical applications. However, there are substantial technical and infrastructure challenges which need to be addressed in order to effectively use them as alternatives to conventional materials. Some of those key challenges are discussed below.

Metal matrix composites require reinforcements in the form of defect free fibers and particles which are often expensive. Hence, the economic production of low cost and high strength reinforcement would be timely. In this regard, the effective utilization of eco-friendly and recycled materials as reinforcement is also recommended.

Fabrication techniques suitable for MMCs are highly complicated when compared to conventional materials. Hence, any research advancements related to the development of user-friendly and environmentally conscious fabrication methods that are capable of fabricating defect free composites would be timely given that these materials are often more brittle than their unreinforced matrix counterpart.

With respect to properties, poor ductility and toughness are the major limitations of MMCs. Although the recent research works have identified some of the possible ways to overcome these limitations through nanoscale reinforcements, thermal treatments, and secondary processing, systematic fundamental investigations linking the process-structure-property relationships are required for commercialization. Similarly, issues concerning the operations such as joining, machining and recycling also require due attention.

Introduction

Metal matrix composites constitute a class of materials, which make a major industrial impact in fields as diverse as aerospace, automotive and electronics. These composites are made up of a metal matrix packed with particles having very different physical and mechanical properties from those of the matrix. MMCs are attractive due to their cost-effectiveness, isotropic properties, and their ability to be processed using similar technology used for monolithic materials. They can provide significantly enhanced properties like higher strength, stiffness and weight savings in comparison to conventional monolithic materials. The micron sized particle reinforced metal matrix composites are widely used in manufacturing sector due to light-weight, superior strength-to-weight ratio, better fracture toughness, improved fatigue, and tensile property, enhanced corrosion resistance to harsh environment. This article provides an overview of the different types of micron sized reinforcing elements used during the synthesis of MMCs (Jawalkar *et al.*, 2017; Clyne and Withers, 1995; Miracle, 2005). Reinforcement selection criteria include density, melting temperature, elastic modulus, tensile strength, thermal stability, coefficient of thermal expansion, size, compatibility with matrix material, and cost (Clyne and Withers, 1995).

Processing Methods

The production methods can be categorized into two major groups: ex situ and in situ. The first synthesis route consists of adding micro-reinforcements to the liquid or powdered metal, while in situ processes refer to those methods leading to the generation of compounds by reaction during processing. Several methods have been developed for ex situ synthesis of MMCs. In particular, the processing methods such as liquid and powder metallurgy were successfully employed. The processing methods utilized to manufacture particulate reinforced MMCs can be grouped depending different processing methods, accordingly the processes can be classified into three categories: (1) liquid phase processes, (2) solid state processes, and (3) two phase (solid-liquid) processes. In liquid phase processes, the ceramic particulates are incorporated into a molten metallic matrix using various proprietary techniques, followed by mixing and casting of the resulting MMC. In melt infiltration processes, a molten alloy is introduced into a porous ceramic preform, utilizing either inert gas or a mechanical device as a pressurizing medium. Solid phase process variably involves the blending of rapidly solidified powders with particulates, platelets or whiskers. In solid-phase processing, the temperature of the matrix during processing rarely exceeds the solidus temperature. This involves blending a matrix, in powder form with a reinforcing phase, under elevated temperatures and pressures. Semi-solid processes involve mixing the reinforcing phases under thermodynamic conditions such that the matrix contains both solid and liquid.

Strengthening Mechanisms

The strengthening mechanisms are divided into (1) Load transfer from the matrix to the hard reinforcements in MMC, (2) The coefficient of thermal expansion mismatch between matrix and the reinforcement particles, (3) Orowan Strengthening mechanisms in reinforced MMCs, (4) Hall-Petch strengthening mechanisms in reinforced MMCs, (5) Elastic modulus mismatch between matrix and reinforcement particles. Deformation mechanisms involve initial accommodation of applied load by slip or shear band formation followed by load transfer among reinforcements and the matrix. Plastic deformation during processing introduces dislocations which might form substructures that could control the flow stress of the metal-ceramic material. These dislocations may be immobilized by the ceramic particulates and thus be retained in the matrix.

The strengthening mechanisms in metal matrix composites have been related to a high dislocation density in the matrix originating from differential thermal contraction, geometrical constraints and plastic deformation during processing. In addition, stress and strain distributions and possible particle fracture or debonding has effects on properties. Among different shapes, a certain shape of reinforcement particle provided better tensile properties for MMCs and, within each shape category, composites with smaller particle size and higher particle content also showed better properties. It was also found that when the reinforcement content was low the effects of shape and size of the particles were negligible. It was noted that the strength and fatigue life increased with the decrease in particle size and increase in volume fraction (Basak *et al.*, 2019; Taya, 1991; Paknia *et al.*, 2016; Wu and Lavernia, 1992).

Table 1 Physical and mechanical properties of potential reinforcements used in MMCs

Properties	Silicon carbide (SiC)	Alumina (Al ₂ O ₃)	Boron carbide (B ₄ C)	Graphite	Titanium boride (TiB ₂)
Density (gm/cm ³)	3.21	3.89	2.52	1.3–1.95	4.58
Melting point (°C)	2830	2072	2350	3600	3230
Thermal conductivity (W/m K)	120–170	35	30–42	25–470	26
Coefficient of Thermal Expansion (10 ⁻⁶ /°C)	4	8.4	5	8.2	8
Hardness (Kg/mm ²)	2800	1440	2900–3580	33.2	2753.23
Tensile Strength (MPa)	1625	240	569	76	373.6

Types of Reinforcement

Metal matrices are most often based on aluminum, magnesium, copper, and steel have successfully been reinforced with various particles and fibers. Although metallic particles are used in some composites, particles of interest here are primarily ceramic, often made from the lighter elements like SiC, Al₂O₃, B₄C, TiB₂ and TiC. **Table 1** shows the physical and mechanical properties of potential reinforcements used in MMCs. Graphite has also been added to aluminum as a dry lubricant and as a chip-breaking phase in machining but has the disadvantage of being weak, resulting in composites with poor mechanical properties. Material behavior of MMCs depends on the type of reinforcement therefore the understanding of relationship between the strengthening behavior and microstructure is a critical issue in developing metal matrix composites. Different organic, inorganic, industrial and agricultural waste which can be used for reinforcement in the metal matrix is highlighted with their feasible applications. Reinforcing elements such as AlN, CeO₂, GNP, Gr, Cu, TiC, TiN, TiB₂, TaC, SiC, Si₃N₄, ZrO₂, ZnO, ZrB₂, WS₂, etc., were widely used to modify the matrix material as per the requirement and use of the process (Bhoi *et al.*, 2020; Kumar *et al.*, 2010).

Silicon Carbide (SiC)

The SiC particles are the most common discontinuous reinforcements in metal matrix composites for its low cost and readily availability. But still gives the composite high strength and elastic modulus. **Fig. 1(a)** shows the Scanning Electron microscopy images of SiC particles and **Fig. 1(b)** shows the microstructure of aluminum 356–15% SiC-infiltrated composite. The improved wear resistance is often the primary feature as well. In the same way as in the case of continuous SiC fibers the possibility of chemical reactions limits the high temperature applications and may cause problems in production. Silicon Carbide (SiC) and silicon fibers are mainly used in aluminum, magnesium, and copper-matrix composites. Most studies concentrated on composite tensile properties, in particular, the stiffness, strength, and ductility at ambient and elevated temperatures. An increasing trend of hardness and impact strength with increase in weight percentage of SiC has been observed (Karvanis *et al.*, 2016). Microstructure shows the uniform distribution of SiC particles in the matrix resulted due to the good quality preform used and the effective penetration of the liquid metal even in minute voids of the preform. **Table 2** shows the Physio-mechanical properties of aluminum metal matrix composites reinforced with SiC. It is shown that the mechanical properties are increasing with increase in silicon carbide content (**Fig. 2**).

The tribological properties of the material are very important. Incorporation of hard second phase particles in the matrix to produce MMCs has also been reported to be more beneficial and economical (Gül *et al.*, 2012). **Fig. 2** shows Microstructure of aluminum 356 – 50% SiC squeeze infiltrated composite (Ozden *et al.*, 2007). Hardness of the matrix alloy improved significantly by adding SiC particles, while density of the composite also increased almost linearly with the weight fraction of particles (Sahin, 2003; Knowles *et al.*, 2014; Chawla, 2012).

Alumina and Aluminosilicate

The alumina-reinforced metal matrix composites find wide application next to silicon carbide-reinforced composites in the areas of automotive and aerospace industries. These composites possess high elevated-temperature strength, wear resistance, damping properties, electrical conductivity, thermal conductivity and coefficient of thermal expansion. The alumina can be in the form of particulates, whiskers and fibers. There is effects on Al₂O₃ particle content and size of particle on the mechanical properties of the composites such as hardness and tensile strength. This trend is due to an increase in the proportion of the hard Al₂O₃ particulates in the composites, which increases the composites resistance to indentation in comparison to the monolithic alloy (Yan *et al.*, 2008). **Fig. 3** shows the optical microstructure of Al6061-aluminosilicate composite reinforced with 15 vol% of fiber by squeeze infiltration processing. Uniform dispersion of aluminosilicate fibers in the matrix is observed without the formation of porosities and cracks owing to the solidification of the composite (Manu *et al.*, 2016).

which is widely used as filler in polymer composites. Micro silica stands out as one of the attractive reinforcement with its distinct advantages like low density coupled with thermal stability as well as other properties that stand equal to other commercial reinforcements. Microsilica ceramic particles are fine in size, semi-transparent, white-colored and high-strength microspheres typically used to improve hardness and abrasion resistant coatings. microsilica particles made of alkali alumino silicate ceramic particles. Composites exhibit a remarkable wear resistance with decreased wear rates at an increased sliding velocity due to the formation of tribolayer containing oxygen and iron on the pin surface and abrasive wear mechanism is observed in the material.

Carbon

Carbon is one of the predominant reinforcements used in the fabrication of aluminum matrix composites. These composites find wide applications in aerospace, defense and electrical applications due to their high specific strength, high-temperature properties and excellent thermal and electrical conductivities. Carbon is reinforced in various forms namely graphite particles, carbon short and continuous fibers, fullerene, carbon nanotubes and graphene. **Fig. 5(a)** shows the SEM morphologies of graphite flakes and the **Fig. 5(b)** graphite infiltrated A356 aluminum composite.

Carbon is a covalently bonded high melting-point solid that is characterized by closed stable electron configuration and high-strength interatomic bonds. Considerable differences exist in the wetting of carbon by liquid metals ([Asthana, 1998a](#); [Rajan *et al.*, 1998](#)) The potential low cost of the constituent materials also suggests that the graphite MMCs may have an economic advantage over other high-performance composite systems. The presence of graphite particles in the matrix alloys increases their seizure resistance and enables them to run under boundary lubrication without failure. Carbon-fiber composites can be produced with matrices of aluminum. Aluminum reacts with carbon to form the carbide Al_4C_3 , which results in poor composite properties when it appears along the fiber/matrix interface. This reaction can be sufficiently controlled during processing to produce material with

Squeeze infiltration processing and structural characteristics of lightweight aluminum-carbon metal matrix composites. Transactions of the Indian National Academy of Engineering, 1–8.

Table 3 Tribological properties of aluminum graphite composites

Material	Hardness (BHN)	Wear rate ($\times 10^{-3} \text{ mm}^3/\text{m}$)	Coefficient of friction μ
Al 6061	63	41	0.91
Al 6061/3 Gr	61	78	0.73
Al 6061/5 Gr	59	83	0.65
Al 6061/9 Gr	55	91	0.6
Al6061/13 Gr	83	101	0.56

Note: Mahdavi, S., Akhlaghi, F., 2011. Effect of the graphite content on the tribological behavior of Al/Gr and Al/30SiC/Gr composites processed by in situ powder metallurgy (IPM) method. Tribology Letters 44, 1–12. Peng, X., Huang, Y., Sun, X., Han, X., Fan, R., 2019. Effect of chromium coated carbon fiber on the thermal and mechanical properties of Cr@Gf/Cr@CF/Al composites. Journal of Materials Science: Materials in Electronics 30, 7226–7233.

attractive longitudinal tensile strength and modulus. **Table 3** shows the properties of aluminum graphite composites by powder metallurgy. The specific modulus of 30 vol% graphite aluminum composite fabricated into structural shapes is three times those of ultrahigh strength aluminum, titanium, and steel alloys, whereas the specific strength is comparable. At 50 vol% fibers, the graphite-aluminum will have a specific modulus four times and a specific strength twice that of structural alloys. However, specific strength alone cannot justify the use of graphite-aluminum composite structures since there are other advanced systems that have equally high specific strengths. Copper-graphite and silver-graphite composites have found applications in electrical brushes and contact strips. Aluminum-graphite composites have been successfully tested as materials for bearings, pistons, and liners in engines and electromechanical machinery and their use resulted in improvements in performance and sometimes reduction in cost (Rohatgi *et al.*, 1993). **Table 4** shows the physical properties of aluminum-graphite composite processed by powder metallurgy technique using pure aluminum as matrix and natural flaky graphite (graphitization degree 98%) as the reinforcement. Density and CTE decreases, while thermal conductivity increases with increase in graphite addition. The composites find potential application in thermal management of electronic and computer systems.

Fig. 6 shows the scanning electron microscopy image of carbon fiber and **Fig. 7** shows the optical microstructures of (1) Carbon fiber fabric/Al 6061 infiltrated composite and (2) cross section of the infiltrated composite. Carbon fibers, however, are inherently weak perpendicular to the fiber axis. Properties of carbon fiber reinforced composites along essentially all directions other than the fiber axis, and also in compression along the fibers, are therefore not very attractive compared to achievements with a strongly bonded ceramic fiber in terms of both modulus and strength. Carbon fibers also conduct electricity and there is galvanic coupling between fiber and matrix. Corrosion of carbon fiber reinforced aluminum or magnesium in wet or moist environments is therefore often very severe. For the reinforcement of aluminum, carbon fibers thus have both advantages and disadvantages compared with ceramic fibers.

Fly Ash

Fly ash particles are one of the potential discontinuous dispersoids used in metal matrix composites. They are low-cost and low-density reinforcement available in large quantities as a left-over by-product from thermal power plants. There are two types of fly ash, specifically, precipitator (solid particle) and cenosphere (hollow particle). The major chemical constituents of fly ash are SiO_2 ,

Table 4 Physical properties of aluminum graphite composite

Material composition	Density (g/cm ³)	Thermal conductivity (W/m-K)	CTE (ppm/K)
Aluminum	2.70	225	24
Al - 10% Graphite	2.65	305	16
Al - 20% Graphite	2.60	396	15
Al - 30% Graphite	2.56	430	13
Al - 40% Graphite	2.50	481	12
Al - 50% Graphite	2.45	523	11
Al - 60% Graphite	2.41	555	10.5
Al - 70% Graphite	2.36	690	10.2
Al - 80% Graphite	2.30	720	10
Al - 90% Graphite	2.27	750	9

Al_2O_3 , Fe_2O_3 and CaO . The fly ash constitutes the alumino silicate glasses containing quartz, mullite, hematite, magnetite, ferrite, spinel, anhydride and alumina. They improve the wear resistance, damping properties, hardness and stiffness and reduce the density of Al alloys.

Fig. 8 shows the optical photomicrographs of A 356–15% fly ash composite processed by modified compo-casting followed by squeeze casting. A linear decrease in the density and ultimate tensile strength and a linear increase in electrical resistivity of Al–12Si–fly ash composites have been observed with increasing dispersoid content. Studies on AK12($\text{AlSi}_{12}\text{CuNiMg}$)/9% Fly ash composites have shown that squeeze casting is more advantageous than gravity casting for obtaining high structural integrity with minimum porosity and these composites show enhanced pitting corrosion than the matrix alloy (Bienia *et al.*, 2003). The average tensile strength in T6 condition for the alloy are 287 and composite is 193 MPa. The reduction in tensile strength in fly ash composites is due to particle fracture and interfacial bonding which is showing in **Table 5**. 12-vol% fly ash reinforced composites exhibit lowest Tensile strength. This low UTS in 12-vol% fly ash reinforced composites is due to the presence of porosity and the formation of second phase particles in the matrix and at particle/matrix interfaces (Surappa, 2008; Ling *et al.*, 2019). Earlier studies on aluminum fly ash composites have also shown the reduction in tensile values for the composites compared to the matrix alloy. **Table 6** shows the density, hardness and tribological properties of Aluminum 2024 Fly Ash Composite. Density values are decreasing with increasing fly Ash content. Also there is an improvement on wear resistance of the composite.

Boron Carbide

Boron carbide (B_4C) is the third hardest material after diamond and cubic boron nitride, which possesses low density, high degree of chemical inertness, high temperature stability, and excellent thermoelectric properties. The atomic structure of boron carbide is rather unique. This unusual structure and bonding is responsible for the excellent thermo-mechanical properties of boron carbide, thus making it a good substitute for many applications (Rajan *et al.*, 1998). Dispersion of B_4C and its interfacial stability is a major issue during its processing (Mahesh *et al.*, 2011).

Fig. 9 shows the SEM micrographs B_4C particles and **Fig. 10** shows the optical micrograph of Al 6061- B_4C particles. This investigation is on the synthesis of B_4C -reinforced 6061 aluminum matrix composite by liquid–metal stir-casting technique under optimized conditions after solving the issues related to the processing, and evaluation of the structural, mechanical, and interfacial characteristics. Interfacial characterization of the composite and the extracted B_4C particles from the matrix has shown the presence of interfacial reaction products such as AlB_2 , Al_3BC , AlB_{12} , and AlB_{10} (Mahesh *et al.*, 2011).

In situ Composites

In situ metal matrix composites refers to the composite in which the reinforcements are formed in situ by exothermal reactions between elements and compounds. Using this approach, MMCs with a wide range of matrix materials including aluminum, titanium, copper, nickel and iron, and second-phase particles including borides, carbides, nitrides, oxides and their mixtures have been produced. Because of the formation of ultrafine and stable ceramic reinforcements, the in situ MMCs are found to exhibit excellent mechanical properties. Compared to the conventional MMCs produced by ex situ methods, the in situ MMCs exhibit the following advantages (1) the in situ formed reinforcements are thermodynamically stable at the matrix, leading to less degradation in elevated-temperature services. (2) The reinforcement matrix interfaces are clean, resulting in a strong interfacial bonding. (3) The in situ formed reinforcing particles are finer in size and their distribution in the matrix is more uniform resulting better

Table 5 Tensile and compression properties of the Aluminum fly ash composites

Material	Tension	Compression	% elongation in tension
A 356	165	458	24

mechanical properties. The in-situ composites show clean interfaces, strong interfacial bonding, a uniform spatial distribution of particles and a narrow particle size distribution. Further structural changes are effected using secondary processes such as mechanical working, infiltration, and controlled solidification ([Kampe et al., 1990](#); [Asthana, 1998b](#)).

Fig. 11(a) shows the microstructure of A390–0.5% Mg centrifugal cast In-situ functionally graded Al composite pistons fabricated by vertical centrifugal casting technique. Higher concentration of primary Si particles gets gradually distributed towards the head region of the piston providing enhanced properties. Magnesium provides substantial strengthening and improvement of precipitation hardening phases of aluminum alloy. Centrifugally cast FGM pistons provide high hardness, thermal resistance and wear properties than that of conventionally gravity cast pistons. Heat treated samples were found to provide superior properties than that of as-cast samples. A higher hardness of 188 BHN was reported in the head portion of the 0.5% Mg A390 FGM piston. Wear test results shows that the outer periphery of the piston is having lower wear rate even at high load (4 kg). Wear resistance gradually decreases from head to skirt portion. These Al FGM pistons containing a large quantity of primary Si particles on the piston head can meet the high temperature requirement and wear resistance of the piston ([Arsha et al., 2015](#)).

Hardness tests were performed on in situ alumina particle reinforced aluminum matrix composite through stir casting. Samples of Al–Al₂O₃ in situ composite, annealed samples of Al– Al₂O₃ in situ composite. Heat treated composite increases the workability and results in the formation of very fine precipitates and increases the strength and hardness. The compression strength of the Al–

Applications

The properties of MMCs can differ by varying the nature of the constituent phases and their volume fractions. MMCs provide great potential for the production of composites with the desired properties for specific applications. Fig. 12 shows the functionally graded aluminum matrix composite prototype components developed and fabricated by centrifugal casting for engineering applications such as Gear wheels, cylinder liner for two wheeler and Brake rotor disc for four wheeler automobiles. Al based metal matrix composites (MMCs) are a class of materials that have proven effective in meeting most of the stringent requirements in applications where the necessary properties are lightweight, high rigidity and moderate strength. An area where substantial weight savings can be achieved by using MMCs is the components of the automotive braking system, such as the disc brakes and calipers. Table 8 describe the properties of reinforcements used in commercial aluminum matrix composites.

SiC reinforced aluminum brake rotors have been used for most modern car models, including Lotus Elise, General Motors EV1, Chrysler Prowler, Volkswagen Lupo 3 L and Toyota RAV4 EV. The Apollo spacecraft, the Skylab, the space shuttles and the International Space Station used AlMMCs and alloys. In such areas requiring mechanical stability, damping, thermal control and reduced weight, aluminum composites consistently surpass other metals. A variety of influential vehicle producers have adopted SiC-reinforced aluminum brake rotors for the widespread use of aluminum composite brake rotors due to the high cost and machinability problems of cast iron. To resolve price and machinability barriers, UWM developed aluminum-silicon carbide-graphite composites, aluminum alumina-graphite and hypereutectic aluminum-silicon graphite alloys with decreased silicon carbide (Nturanabo et al., 2019). Another application of MMCs in the automotive area is in diesel piston crowns. This involves incorporation of short fibers of alumina or alumina and silica in the crown of the piston. The conventional diesel engine piston has an Al–Si casting alloy with crown made of a nickel cast iron. The replacement of the nickel cast iron by aluminum matrix composite resulted in a lighter, more abrasion-resistant, and cheaper product. Continuous alumina fiber

reinforced Al composites are used to make power transmission cables. The cable consists of a composite core, consisting of $\text{Al}_2\text{O}_3/\text{Al}$ composite wrapped with Al–Zr wires. The composite core bears most of the load as it has much higher stiffness and strength (Rohatgi *et al.*, 2020).

Conclusion

This article has primarily been concerned with the factors influencing relationship of composites with micron sized reinforcements and the microstructural-mechanical properties. The effects of microstructure, particle distribution, volume fraction of reinforcement and the matrix have been reviewed. The physical and mechanical properties of micron sized reinforcements were also discussed with particular emphasis on strengthening mechanisms. The interface formed between the matrix and the reinforcement has a critical effect on subsequent mechanical behavior of the composite. Substantial progress in the development of light metal matrix composites has been achieved in recent decades, so that they could be introduced into the most important applications. This group of material becomes interesting for constructional and functional applications, if the properties of conventional materials either does not reach the increased standards of specific demands, or is the solution of the problem. The technology of MMCs is in competition with other modern material technologies. The advantages of the composite materials are realized when there is a reasonable cost performance relationship in the component production. The use of a composite material is essential if a special property profile can only be achieved by application of these materials.

An Insight Into Metal Matrix Composites With Nano Size Reinforcement

Massoud Malaki, Isfahan University of Technology, Isfahan, Iran

An Overview

Composites are a pivotal category of advanced materials providing unique capability to improve selected properties. The improvement in targeted properties can be controlled, for example, through size, shape, and the amount of reinforcing agent. The research in composites primarily started in 1970s where the researchers tried to unify the metallic materials (as matrix) with ceramics (as reinforcement) where both continuous and discontinuous micro-sized strengthening materials were utilized through a number of manufacturing routes such as stir casting, powder metallurgy, rheocasting, etc. (Ceschini *et al.*, 2017a; Lloyd, 1994; Gupta and Wong, 2015).

Although conventional composites (i.e., those filled with the micron-sized reinforcements) may provide many benefits with respect to their neat alloys; however, owing to the micron size of the additive materials, these composites have a series of significant drawbacks such as excessive tool wear rate while machining, poor ductility, and low fracture toughness as compared to the unfilled matrices (Malaki *et al.*, 2019; Suresh, 2013). To deal with the mentioned limitations and to fabricate novel composites with simultaneously improved strength and ductility at both room and elevated temperatures, the size of strengthening agent has been reduced to the nanosized levels (< 100 nm) in order to provide metal matrix nanocomposites (MMNCs). Since 2000, the interest in using nano-sized reinforcing agent in metals such as Al, Mg, Ti, Ni, and Cu sharply increased. The reinforcements were first from oxides, carbides, nitrides or borides, but carbon allotropes such as buckyballs, CNTs, MWCNTs, graphene, and other carbon based nanoplatelets were then considered in the investigations (Calvert, 1999; Suárez *et al.*, 2016; Malaki *et al.*, 2019; Ceschini *et al.*, 2017a). Using nanosized reinforcements, the properties mentioned below can be improved:

- (1) Mechanical strengths at room or elevated temperatures,
- (2) Fatigue,
- (3) Fracture toughness,
- (4) Creep,
- (5) Wear and corrosion,
- (6) Thermal properties,
- (7) Damping,
- (8) Machinability.

The two prevalently reported damage mechanisms in the micro-sized metal matrix composites are particle breakage and reinforcement-matrix interfacial debonding; these two mechanisms are substantially minimized in the nano-composites (Suresh, 2013). Using nano-sized strengthening reinforcements, ductility and fracture toughness behaviors improve, being highly demanded in special applications such as biomaterials (Hassan and Lewandowski, 2018; Ceschini *et al.*, 2017a; Goh *et al.*, 2008; Zhong *et al.*, 2007; Gupta and Wong, 2015; Ceschini *et al.*, 2017b; Goh *et al.*, 2006).

Regardless of reinforcement and matrix properties, manufacturing and processing conditions are of crucial importance as the final properties are directly influenced by the homogeneity and the dispersion quality of the reinforcing agent (Ceschini *et al.*, 2017b; Malaki *et al.*, 2019). Furthermore, most of the reinforcing particles such as ceramic particles have poor wetting conditions, so a careful consideration should be made in order to achieve good interfacial bonding between matrix and reinforcement surfaces. For instance, during stir casting, ultrasonic dispersion of ceramic or carbide nanoparticles in molten matrix, e.g., Al, is a method of improving wettability (Malaki *et al.*, 2019; Abdullah *et al.*, 2012; Eskin and Eskin, 2015).

Metal matrix nanocomposites dedicated with excellent combinations of material and mechanical properties are inaugurating new applications in different engineering and biomedical fields (Gupta and Meenashisundaram, 2015). For instance, nano-bio-composites provide enhanced specific strength, acceptable biocompatibility, and biodegradation behaviors as well as cell growth capability typically demanded in biomaterials like orthopedic implants (Gong *et al.*, 2015; Gupta and Meenashisundaram, 2015; Paul and Sharma, 2006). In addition, light-weight and high-strength are simultaneously needed in many industrial applications, like those used in motorbikes in order to save cost, reduce weight, and improve performance (Eskin and Eskin, 2014; Gupta and Wong, 2015).

Strengthening Mechanisms

Reinforcements may change dislocation density, structure, and movement and hence may considerably influence the mechanical performance of the fabricated composites (Hamedan and Shahmiri, 2012; Ceschini *et al.*, 2017a; Shin and Bae, 2018; Malaki *et al.*, 2019). Although the nature of the MMNCs has not yet been fully understood, many efforts have been made to find out the role played by the strengthening mechanism(s) and propose constitutive modeling techniques (Baisane *et al.*, 2015; Ceschini *et al.*, 2017b; Habibnejad-Korayem *et al.*, 2009; Zhang and Chen, 2008; Kim *et al.*, 2013; Sanaty-Zadeh, 2012). Here are some of the most important strengthening mechanisms.

Orowan

Unlike those traditional composites reinforced by coarse micron-sized particles having relatively large interparticle distances, nanocomposites are with very closely spaced nano-particles posing an effective strengthening mechanism, i.e., Orowan (Ceschini *et al.*, 2017b; Habibnejad-Korayem *et al.*, 2009; Zhang and Chen, 2008; Zhang and Chen, 2006). The effect of Orowan strengthening is more pronounced in case very fine particles are homogeneously well-dispersed and well-distributed throughout the bulk of composite (Malaki *et al.*, 2019; Zhang and Chen, 2008; Zhang and Chen, 2006). As the dislocations reach to a reinforcing hard particle, e.g., a ceramic nanoparticulate, they first bend and reconnect with themselves on the other side creating a kind of dislocation loop around the reinforcement particles (Ceschini *et al.*, 2017a,c). The dislocation itself can then continue to propagate through the host matrix. While Eq. (1) presents the contribution of Orowan strengthening to the strength (Lloyd, 1994), the interparticle space, λ , is given by Eq. (2) wherein d_p is the average diameter of the nanoparticles, b the Burgers vector, G_m the shear modulus, and V_p the vol% fraction of reinforcing agent (Malaki *et al.*, 2019):

$$\Delta\sigma_{OR} = \frac{0.13bG_m}{\lambda} \ln \frac{d_p}{2b} \quad (1)$$

$$\lambda = d_p \left[\left(\frac{1}{2V_p} \right)^{1/3} - 1 \right] \quad (2)$$

It was shown that the contribution of Orowan strengthening is substantially diminished when the nanoparticles are aggregated in clusters. Below 100 nm particle size, the contribution is particularly effective and increases as the particle size decreases up to a critical value (Malaki *et al.*, 2019). The critical size for the Al_2O_3 -reinforced magnesium matrix nanocomposite and Y_2O_3 -reinforced titanium matrix composites is ~ 5.44 times Burger vector (Ceschini *et al.*, 2017a,b).

Hall-Petch

The addition of nano particles leads to a microstructural grain refinement and hence an increased yield strength is expected. This increase in yield strength can be presented by Eq. (3), called the Hall-Petch equation (Hall, 1951; Petch, 1953) and Eq. (4) (Kim *et al.*, 2013) where σ_y is the yield strength, σ_0 the friction stress that allows dislocations to move on slip planes in a single crystal in the absence of any strengthening mechanisms, k_y the stress concentration factor, and D the average grain size. Also, D_{MMNC} and D_0 are the grain sizes of the nanocomposite and the unreinforced alloy:

$$\sigma_y = \sigma_0 + k_y D^{-1/2} \quad (3)$$

$$\Delta\sigma_{GR} = k_y \left(\frac{1}{\sqrt{D_{MMNC}}} - \frac{1}{\sqrt{D_0}} \right) \quad (4)$$

The contribution of grain refinement was found to be low in some cases (Goh *et al.*, 2007) or it was omitted by some others (Zhang and Chen, 2006, 2008); however, Habibnejad-Korayem *et al.* (2009) observed more than 15% contribution to the final strength of Al_2O_3 reinforced magnesium matrix nanocomposite. In 2013, Kim *et al.* (2013) reviewed the magnesium metal matrix nanocomposites where they concluded that grain refinement is a main factor influencing the total strength of many magnesium matrix composites.

Mismatch in the Coefficient of Thermal Expansion (CTE)

After nano-reinforcements are stirred in a composite slurry, stresses appear at the interface after it is left to cool down, usually due to significantly different coefficients of thermal expansion (CTEs) between the nanoparticles and the host metal. The mentioned difference in CTEs provides geometrically necessary dislocations (GNDs) by which the differences of the CTEs could be accommodated. The GNDs-induced mechanical strength can be described by Eq. (5) (Dai *et al.*, 2001a; Vogt *et al.*, 2009) wherein β is the dislocation strengthening coefficient, ΔT the difference in temperature, and $\Delta\alpha$ the difference in CTE:

$$\Delta\sigma_{CTE} = \sqrt{3} \beta G_m b \sqrt{\frac{12V_p \Delta\alpha \Delta T}{b d_p}} \quad (5)$$

It was shown that the contribution of very small reinforcing agent to the strength increase due to mismatch in the CTE is somewhat negligible (Dunand and Mortensen, 1991; Redsten *et al.*, 1995).

Mismatch in the Young's Modulus

Similar to the mismatch in CTEs, GNDs can also be generated due to differences in the Young's modulus (MYD). Dai *et al.* (2001a) proposed Eq. (6) to describe the contribution of MYD in mechanical strength improvement. α is material coefficient and ε is the bulk strain of the composite:

$$\Delta\sigma_{Mod} = \sqrt{3} \alpha G_m b \sqrt{\frac{6V_p \varepsilon}{b d_p}} \quad (6)$$

Load-Bearing

The shear transfer of applied load from the matrix to the reinforcing agent is named as load-bearing/transferring effect. This kind of strengthening mechanism can be dominant provided that a strong cohesion is obtained between the reinforcement and matrix (Malaki *et al.*, 2019). Since nanocomposites contain only a very low volume fraction of the reinforcements (<5%), the effect of load-bearing was found to be low (Goh *et al.*, 2007) or even negligible (Habibnejad-Korayem *et al.*, 2009) as shown in Eq. (7) (Ramakrishnan, 1996); σ_m is the yield strength of the matrix:

$$\Delta\sigma_{\text{Load}} = \frac{1}{2}V_p\sigma_m \quad (7)$$

Modeling

Since 1980s, many modeling approaches have been developed so far among which the following three models are frequently used in order to estimate the yield strength of MMNCs (Kim *et al.*, 2013):

- Arithmetic summation,
- Quadratic summation,
- Compounding methods.

The first two models, arithmetic and quadratic summations, are based on dislocation theory applied to single crystals (Ceschini *et al.*, 2017a,b). The third model, i.e., compounding method, was originally proposed by Nardone and Prewé (1986). Based on modified shear lag, the compounding methods treat all mechanisms as load-bearing effects being represented by a summation of strengthening factors. In order to calculate the effects of strengthening mechanisms, the rule of addition was firstly introduced by Arsenault (1984); this model overestimates the yield strength in some cases (Goh *et al.*, 2007). Ramakrishnan (1996) integrated a modified shear lag approach and an improved dislocation density method wherein the effects of load transfer and the coefficient of thermal expansion are taken into account. Zhang and Chen (2006) modified the Ramakrishnan's model in order to include Orowan strengthening effect in the calculation, being specifically significant in the case of MMNCs.

The effects that reinforcing nanoparticles have on mechanical strength typically include some different strengthening mechanisms taking action in varying levels whose contributions to the final strength improvement could be summed up by Eq. (8) or the root of the sum of the squares could be considered as a total effect (Eq. (9)) (Goh *et al.*, 2007; Zhong *et al.*, 2007). Eq. (8) is usually employed when the reinforcing effects are supposed to be independent, while Eq. (9) is commonly utilized when the individual mechanisms do not behave independently:

$$\Delta\sigma_{\text{Total}} = \Delta\sigma_{\text{GR}} + \Delta\sigma_{\text{OR}} + \Delta\sigma_{\text{CTE}} + \Delta\sigma_{\text{Mod}} + \Delta\sigma_{\text{Load}} \quad (8)$$

$$\Delta\sigma_{\text{Total}} = \sqrt{\Delta\sigma_{\text{GR}}^2 + \Delta\sigma_{\text{OR}}^2 + \Delta\sigma_{\text{CTE}}^2 + \Delta\sigma_{\text{Mod}}^2 + \Delta\sigma_{\text{Load}}^2} \quad (9)$$

Depending on materials, processing conditions, or manufacturing routes, some of these strengthening effects can be omitted from the calculations. For an instance, the effect of load transferring effect is insignificant when using a very low volume fraction of reinforcing particles; the effect of Orowan strengthening can be neglected when the particle size is not adequately small. Although many believe the model described in Eq. (9) is best fit with the experimental data (Goh *et al.*, 2007; Dai *et al.*, 2001a; Sanaty-Zadeh, 2012), still there is no general formula to calculate the strength of MMNCs (Kim *et al.*, 2013).

It should be noted that no agglomeration or clustering has yet been taken into consideration by the current models. Post-processing techniques such as mechanical deformation utilized in many studies usually increase dislocation density and hence the final yield strength improvement may be influenced as well by the work hardening caused by these post-processing methods.

Manufacturing and Processing Techniques

Fabrication of MMNCs is of crucial importance as the final performance is significantly affected by the manufacturing parameters (Malaki *et al.*, 2019; Ceschini *et al.*, 2017b; Suresh, 2013; Eskin and Eskin, 2015). Here are the most important fabrication methods for the MMCs.

Stir Casting

One of the most prevalent, simple, fast, and even economic methods of producing MMCs is stir-casting wherein the reinforcing agent is added to a metal melt followed by a stirring process to achieve a homogenously distributed particles in the metal matrix. Aluminum and magnesium alloys are the two metals extensively used as a matrix being reinforced by a wide variety of materials ranging from ceramics, oxides, and nitrides to carbon allotropes such as nanotubes and graphene (Hemanth, 2009; Hamedan and Shahmiri, 2012; Sajjadi *et al.*, 2011; Suresh *et al.*, 2011). Apart from several advantages, stir casting has a few major drawbacks from which poor wetting condition of nanoparticles in a metal melt, the tendency of particles to be clustered or agglomerated due to high interparticle van der Waals, and the porosities (e.g., voids and cavities) are of the most important items (Cao *et al.*, 2008;

Fig. 1 Schematic diagram of disintegrated melt deposition setup. Reproduced from Gupta, M., Wong, W., 2015. Magnesium-based nanocomposites: Lightweight materials of the future. *Materials Characterization* 105, 30–46.

Donthamsetty *et al.*, 2009; Akbari *et al.*, 2013). Ultrasonic treatment is sometimes applied to improve wettability and dispersion quality (Malaki *et al.*, 2019). To minimize casting voids and porosity, cast materials are usually further processed by forging, extrusion, swaging, or other plastic deformation methods (Malaki *et al.*, 2019; Goh *et al.*, 2007; Rozak *et al.*, 1992; Goh *et al.*, 2008; Hassan and Lewandowski, 2018).

Disintegrated Melt Deposition (DMD)

Based on stir casting principles, the composite slurry is first prepared in a crucible and then passed through a nozzle onto a metallic substrate at a superheated temperature under the protection of an inert gas jet. Fig. 1 shows the schematic of DMD process. DMD is mainly used to produce magnesium matrix composites (Goh *et al.*, 2006; Srivatsan *et al.*, 2012; Ho *et al.*, 2004; Goh *et al.*, 2008, 2007). For example, Srivatsan *et al.* (2013) could fabricated AZ31 reinforced 1.5 vol% Al_2O_3 (50 nm size) using DMD wherein the ingots were post-extruded resulting in a final product with much finer microstructure and enhanced mechanical performance than that of un-reinforced AZ31.

Semi-Solid Casting (SSC)

Semi-solid casting is a die casting method, wherein a metal with liquid/solid state is injected into a mold. Casting in this condition requires lower power and the resultant product has less voids and porosities, hence demands less post-processings such as machining or mechanical plastic deformation in order to improve microstructure. On the other hand, globular microstructure is not easy to obtain in SSC. Zinc alloy AC43A nanocomposite with 0.5 wt% SiC β nanoparticle additions were cast at a 30% solid fraction (de Cicco *et al.*, 2009). AM60/SiC nanocomposite was obtained in a uniform microstructure form via semi-solid casting and a 19.3% and 7.9% increase in the elongation and the UTS, respectively, was discerned through addition of 0.1 vol% of the nanoparticles (Wang *et al.*, 2006).

Fig. 2 Comparison of mechanical performance among liquid cast AC43A alloy, liquid cast AC43A/0.5 wt% SiC nanocomposite, and AC43A/0.5 wt% SiC nanocomposites produced by SSC at 30% solid fraction: (a) ductility and (b) strength. Fig. 3 Different steps toward the production of Al-Si₃N₄ nanocomposites. Reproduced from Matli, P.R., Ubaid, F., Shakoor, R.A., *et al.*, 2017. Improved properties of Al-Si₃N₄ nanocomposites fabricated through a microwave sintering and hot extrusion process. RSC Advances 7, 34401–34410.

de Cicco *et al.* (2009) and de Cicco (2009) dealt with the semi-solid casting of zinc alloy AC43A nanocomposite with 0.5 wt% SiC β reinforcement and a solid fraction of 30% wherein they observed reduced shrinkage, increased ductility & strength, and nanoparticle induced grain refinement producing a globular structure without having to apply additional material/mechanical processings. Fig. 2 illustrates the ductility as well as strength obtained under different conditions showing both strength and ductility improvement in case SSC is used to fabricate the composite.

Powder Metallurgy (PM)

Powder metallurgy consists three distinct steps, i.e., (1) mixing metal and reinforcement powders, (2) powder compaction to produce green materials, and (3) sintering usually followed by a deformation process such as hot extrusion (Matli *et al.*, 2017). As a solid-state process, powder metallurgy has a lot of advantages including the following items:

- (1) Near-net shape parts are commonly produced by PM.
- (2) A considerable weight fractions of the nanoparticles can also be integrated.
- (3) PM can be used in batch production systems such as automotive industries.

A wide variety of materials have been used as matrix or reinforcing agent in order to produce different nanocomposites based on PM; for instance, Matli *et al.* (2017) employed a novel MW sintering followed by extrusion at elevated temperatures to develop a Si₃N₄ reinforced nanocomposite with different vol% of 0.5%, 1.0%, and 1.5% (Fig. 3); Simões *et al.* (2017) fabricated CNTs reinforced aluminum and nickel matrix composites with 0.5–2.0 wt%; van Pham *et al.* (2011) produced a CNT reinforced

Fig. 4 Schematic of the ball milling process (a). The used balls are hitting the reinforcements and the matrix powder material (b), welding and integrating the two components (c) and bounce of the powder particle to restart this process again at another spot (d). Reproduced from Suárez, S., Reinert, L., Mücklich, F., 2016. Carbon nanotube (CNT)-reinforced metal matrix bulk composites: Manufacturing and evaluation. *Diamond and Carbon Composites and Nanocomposites*. InTech.

nanocomposite having 0–3.5 wt% CNTs; Akbarpour *et al.* (2014) developed SiC nanoparticles reinforced copper. All these papers reported that the addition of nano reinforcing agents could improve mechanical performance.

A branch of powder metallurgy involves mechanical mixing during which a high energy ball milling process is utilized wherein the cold welding, fracture, and re-welding of the particles occur (Suryanarayana and Al-Aqeeli, 2013; Suryanarayana, 2011, 2001). In particular, this practice is favorable while producing those composites reinforced by nano-sized ceramic particles for breaking up the agglomerates and homogeneously distributing reinforcements throughout the base matrix (Ye *et al.*, 2006). Rotational speed, time of milling as well as the ratio of ball-to-powder are of the most important parameters during ball milling (Fig. 4).

Friction Stir Processing (FSP)

Evolved from the basic principles of friction stir welding (FSW), FSP has now been widely utilized in different researches and industrial sectors where a locally intense severe plastic deformation is applied on the material leading to improved microstructural features and mechanical properties (Arora *et al.*, 2012). The required deformation is commonly provided by a non-consumable cylindrical pin being forcibly inserting into a groove filled with the pre-determined weight fraction of the nanoparticles (Morisada *et al.*, 2006; Lee *et al.*, 2006; Shafiei-Zarghani *et al.*, 2009; Yang *et al.*, 2010; Sharifitabar *et al.*, 2011; Asadi *et al.*, 2011; Mazaheri *et al.*, 2011; Hsu *et al.*, 2006, 2005; Zhang *et al.*, 2011; Bauri *et al.*, 2011); the pin rotates in a stirring movement, heats up the processing region, and disperses the particles within the adjacent base metal (Fig. 5). This process has mostly been used in the fabrication of light-weight metal matrix (e.g., aluminum and magnesium) nanocomposites (Alizadeh *et al.*, 2013). It should be noted that the uniform distribution of nano-reinforcing agent and final surface quality are the two challenges with the FSP (Bauri *et al.*, 2011; Zhang *et al.*, 2011).

Morisada *et al.* (2006) investigated the optimum tool speed of FSPed multi-walled CNTs reinforced magnesium matrix (AZ31) nanocomposites; it was shown that the synergistic effects of FSP and the addition of nano MWCNTs could improve the mechanical strength and refine the microstructure significantly at the pin rotation of 1500 rpm and traverse motion of 25 mm/min.

Lim *et al.* (2009) employed FSP to fabricate multi-walled CNT reinforced aluminum alloy where they found that increasing the pin speed from 1500 and 2500 rpm and the pin penetration depth promotes the dispersion quality of the reinforcing particles; however, fully homogeneity could not be obtained when the MWCNTs are fractured and or tangled during the processing. It is believed that increasing FSP passes could further improve the dispersion and the homogeneity of the particles within the metal matrix (Lee *et al.*, 2006).

Accumulative Roll Bonding (ARB)

ARB is a process by which metal matrix nanocomposites can also be produced. ARB is a severe plastic deformation (SPD) process wherein a stack of sheets are rolled, sectioned, piled a few times to produce final layered materials (Saito *et al.*, 1998; Ghalehbandi *et al.*, 2019). To further improve the ARBed materials, nano-reinforcing particles are embedded between the layers (Alizadeh *et al.*, 2013; Darmiani *et al.*, 2013). As shown in Fig. 6, the process involves the following steps: (1) surface treatment and wire brushing

Fig. 5 Fabrication of metal matrix nanocomposite by friction stir processing (FSP). Reproduced from Sunil, B.R., Reddy, G.P.K., Patle, H., Dumpala, R., 2016. Magnesium based surface metal matrix composites by friction stir processing. *Journal of Magnesium and Alloys* 4, 52–61.

Fig. 6 Schematic representation of accumulative roll bonding (ARB) for the fabrication of metal matrix nanocomposites.

in order to remove contaminants and unwanted layers of oxides and so on, (2) adding reinforcing particles between the sheets, (3) stacking, (4) rolling the sheets up to a significant thickness reduction, and finally (5) cutting the ARBed specimen and annealing (if needed); the process can be repeated many times (Darmiani *et al.*, 2013; Ceschini *et al.*, 2017a,b).

To date different kinds of reinforcing agents, e.g., W (Amirkhanlou *et al.*, 2013; Liu *et al.*, 2013), WC (Liu *et al.*, 2012), SiO₂ (Hashemi *et al.*, 2012), CNT (Karimi *et al.*, 2016), SiC (Amirkhanlou *et al.*, 2011; Jamaati *et al.*, 2011; Alizadeh and Paydar, 2010),

TiO₂ (Soltani *et al.*, 2012), Al₂O₃ (Jamaati and Toroghinejad, 2010), and B₄C (Yazdani and Salahinejad, 2011) have been used in the reinforced ARBed aluminum composites. For ARB has successfully been utilized to fabricate magnesium matrix nano-composite (for instance, CNT reinforced Mg) (Lv *et al.*, 2017) as well those composites with different material matrices (for example, Al–Al₂O₃–Mg) (Abbasi and Sajjadi, 2018).

Homogenous dispersion and the number of ARB passes seem to have a significant effect on the output mechanical performance (Jamaati *et al.*, 2012). Work hardening, grain refinement, and more uniform distribution of reinforcing particles are the main factors affecting the final ARB products (Ceschini *et al.*, 2017a,b; Jamaati *et al.*, 2011; Jamaati and Toroghinejad, 2010). For instance, the mechanical property of WO₃ (1.0, 1.5, and 2 vol. fractions) reinforced aluminum nanocomposites significantly enhanced upon 12 ARB passes (Khabushan and Bonabi, 2017).

Summary and Conclusion

Light-weight high-strength metal matrix nano-composites (MMNCs) can be used in a wide variety of applications, e.g., aerospace, automotive, and biomedical engineering, owing to their sustainability, increased specific strength/stiffness, enhanced elevated temperature strength, improved wear or corrosion resistance. Metal matrix nanocomposites are commonly those light-weight metals like aluminum or magnesium that are usually reinforced by ceramic particulates, carbon allotropes, elementals, oxides, nitrides, etc. Due to nano-sized dimensions, nanoparticles have a very high aspect ratio, make them to easily agglomerate due to interparticle interactions such as van der Waals. Using well-dispersed fine particles within the host matrix leads to improve strength and ductility simultaneously which is too hard to obtain in micro-composites. It is repeatedly reported that those composites reinforced by smaller particle size exhibit far better mechanical properties such as improved fatigue strength (Hassan and Lewandowski, 2018, 2014; Xia *et al.*, 2019; Ceschini *et al.*, 2017a,b; Malaki *et al.*, 2019). To fabricate the MMNCs, many manufacturing techniques have already been developed, e.g., solid-state processing techniques such as powder metallurgy, liquid state processing routes such as stir casting and semi-solid-state processing methods. To date, a wide variety of particles with different shapes, sizes, and properties have been utilized in MMNC production systems from which ceramic nanoparticles were frequently used, probably due to superior mechanical strength, excellent wear behavior, and thermal stability of ceramic particles. Particles with smaller size. Extensive research investigations are now being conducted to further develop the MMNCs and the technological issues, all trying to fabricate and commercialize high performance metal matrix nanocomposites.

Introduction

Magnesium, being the lightest structural metal is an excellent candidate for weight critical applications (Avedesian and Baker, 1999; Pekguleryuz *et al.*, 2013). Although magnesium (Mg) exhibits some of the interesting attributes such as low density, high specific resistance, good castability, and excellent machinability, its application in pure form is limited due to the inherent limitations such as poor absolute strength, deformability and corrosion susceptibility (Mordike and Ebert, 2001). While the alloy making with Al, Zn, Zr, and RE additions tends to overcome most of these limitations, the specific stiffness and strength properties are improved by introducing the desired amount of ceramic reinforcements in the form of fibers or particles (Kainer *et al.*, 2010). Extensive researches have been conducted in this regard to develop new light weight Mg alloys and their composites (Gupta and Sharon, 2010; Sankaranarayanan and Gupta, 2015a).

In general, the thermally stable reinforcement phases act as nucleation sites for Mg-grains and introduce stress fields due to a mismatch in thermal expansion behavior (Ibrahim *et al.*, 1991; Srivatsan *et al.*, 1995; Malaki *et al.*, 2019). Both the effects inhibit the dislocation motion to result in better strength properties. Recently, the use of nanoscale ceramic particles also received extensive attention owing to their dispersion strengthening benefits (Gupta and Wong, 2015; Sankaranarayanan and Gupta, 2015; Malaki *et al.*, 2019). In most reports, the incorporation of dilute volume fraction of nano-sized reinforcements also enhanced the ductility unlike the micron sized particles or fibers. Similar benefits were also reported for metallic reinforcements with limited/no solubility in Mg (Hassan and Gupta, 2002; Wong and Gupta, 2007; Fida Hassan *et al.*, 2015b).

Some of the published literature in open public domain also report the positive influence of hybrid reinforcements in improving the mechanical properties of Mg (Ugandhar *et al.*, 2006; Habibi *et al.*, 2011; Sankaranarayanan *et al.*, 2011b, 2013; Rashad *et al.*, 2015b; Sahoo *et al.*, 2018). In some of these studies, the hybrid reinforcements were also pre-processed using solid state powder techniques like ball-milling and the end properties of MMCs were strongly influenced by factors such as: the type of processing methods, the matrix and reinforcement constituents, the shape and volume fraction of the reinforcements and the method of reinforcement preparation (Sankaranarayanan *et al.*, 2011b).

In view of this, an attempt is made in this article to document the properties of magnesium-based metal matrix composites containing hybrid reinforcement placing special emphasis on the processing methods.

Melt Infiltration and Squeeze Casting of Magnesium Composites Containing Hybrid Reinforcements

The idea of hybrid (fiber + particle) reinforcement addition to Mg matrix was first proposed by Schröder and Kainer (1991) as an economical alternative to expensive ceramic fibers. Here, the Mg hybrid composites were fabricated by the liquid metal infiltration of preforms containing Al_2O_3 short fibers and SiC particles using a high temperature Mg-2.5Ag-2RE-0.6Zr alloy as the matrix material (as illustrated in Fig. 1). The developed hybrid composites were rationalized with lower costs and more isotropic properties (Fig. 2) compared with fiber reinforced composites produced using squeeze casting methods.

Asano and Yoneda (2008a,b) also used the infiltration technique to investigate the effect of Si addition on the properties of Saffil short fibers reinforced AZ91D composites. While the reaction between Si particles and molten Mg results in the in-situ formation of Mg_2Si particles (as illustrated in Fig. 3), the introduction of red phosphorous (P) or CaF_2 promoted the refinement of Mg_2Si particles. Further, the composites showed better tensile strength for in-situ Mg_2Si particle reinforced Saffil fibers/AZ91D composites in the temperature range from 293K to 523K (Fig. 4).

In a similar study (Babu *et al.*, 2010), AM50 alloy-based Mg composites containing Al_2O_3 short fibers and graphite nano-fibers (GNF) were produced using the melt-infiltration technique. The results of mechanical characterization in this study (Fig. 5) showed improvement in hardness, tensile strength, and compressive strength of composites up to a threshold of 10% volume fraction GNF. However, beyond 10 vol%, agglomeration of GNFs occurred (Fig. 6). In another study (Babu and Kang, 2010), the same authors, reported the nanomechanical properties of AM50/ Al_2O_3 /sf-GNF hybrid composites based on continuous stiffness measurements (CSM). The comparison of measurements from different locations such as GNFs/ Al_2O_3 /sf region, Al_2O_3 /sf region, GNFs cluster, and Mg matrix showed relatively larger modulus and hardness values at the GNFs/ Al_2O_3 /sf interface (Table 1).

Kumar *et al.* (2005, 2007) also used the squeeze casting method to develop AE42 alloy based hybrid composites reinforced with Saffil short fibers and SiC particles. The developed composites were investigated for various properties including thermal cycling, impression creep, sliding wear and corrosion. While the results of thermal cycling studies showed a reduction in the CTE

Materials Science and Engineering A. 135, 33–36. Available at: [https://doi.org/10.1016/0921-5093\(91\)90532-R](https://doi.org/10.1016/0921-5093(91)90532-R).

Fig. 2 Mechanical properties of Mg based Composites reinforced with Saffil fibers and SiC particles reported by Modified from Schröder, J., Kainer, K.U., 1991. Magnesium-base hybrid composites prepared by liquid infiltration. Materials Science and Engineering A. 135, 33–36. Available at: [https://doi.org/10.1016/0921-5093\(91\)90532-R](https://doi.org/10.1016/0921-5093(91)90532-R).

values with increasing amounts of SiC particles, the experimental values along the transverse direction showed a positive deviation from linearity above 215°C as shown in Table 2. The same was attributed to the relaxation of residual compressive strain from the squeeze casting process (Kumar *et al.*, 2005, 2007). This study also highlighted the complex interaction between the Saffil short fibers and SiC particles resulting in a much reduced CTE value when compared to the calculated ones assuming a simple rule of mixture.

In a different study, the same group reported the impression creep response of AE42/Saffil fibers-SiC composites (Mondal and Kumar, 2008, 2009b). The results highlighted a normal creep behavior (i.e., strain rate decreasing with strain and then reaching a steady state) of developed hybrid composites at all the stresses employed at 175°C, and up to 80 MPa stress at 240°C (Fig. 7). However, above 80 MPa at 240°C, the creep behavior was found to be reverse (i.e., strain rate increasing with strain, then reaching a steady state and then decreasing). Similar reverse creep behavior associated with fiber breakage was also reported for all the stress levels at 300°C. Based on the calculated true stress exponent values, the dominant creep mechanisms

of developed hybrid composites were reported as viscous glide and dislocation climb. While the creep rate of all the composites was generally higher in transverse direction compared to the longitudinal direction, the hybrid composites exhibited comparable creep resistance as that of the composite containing only Saffil short fibers. Improvement in creep properties due to hybrid reinforcements was also reported by Svoboda *et al.* (2007) in case of a squeeze cast AZ91 composite reinforced with 7 vol % short carbon fibers and 15 vol% SiC particulates (Fig. 8). However, the same study also reported no benefits due to hybrid (carbon fiber + SiC particles) reinforcement for QE22 matrix alloy.

Available at: <https://doi.org/10.4028/www.scientific.net/msf.783-786.1530>.

Mondal and Kumar (2009a, 2014) also investigated the dry sliding characteristics using a pin-on-disc set up at a constant sliding distance and sliding velocity, 2.5 km and 0.837 m/s respectively, for the load range 10–40 N. While the results showed an increase in the wear rate with respect to the applied load, the hybrid composites exhibited lower wear rate at all the loads when compared to the AE42 matrix alloy and the composite reinforced with only Saffil short fibers (Fig. 9). From the microstructural observations, the authors also confirmed the dominant wear mechanism as abrasion in all the materials as the worn-out surface of composites displayed fractured Saffil short fibers in addition to the severe plastic deformation of the surface layers. Further, in case of the hybrid composite, the micrographs showed intact SiC particles with significant amount of iron which confirmed the formation of an iron-rich transfer layer to delay the fracture of Saffil short fibers even at the highest load employed (Fig. 10).

The same authors (Mondal *et al.*, 2015) also reported the corrosion behavior of AE42 hybrid composites containing Saffil short fibers and SiC particles in various combinations. In this study, the composite containing Saffil short fiber alone exhibited a slightly better corrosion resistance when compared to the hybrid composites containing both Saffil short fibers and SiC particles. However, there was no specific trend reported on the SiC particle content and the poor corrosion resistance of the composites was attributed to the irregular and loose surface films (Fig. 11).

Available at: <https://doi.org/10.1002/maco.201408071>.

In a similar study, the squeeze cast AM60 based composites containing Al_2O_3 reinforcements in the form of fibers and / or particles were investigated for the mechanical behavior and microstructure (Zhang *et al.*, 2014). The results showed an improvement in the hardness and the tensile strength of Mg composites due to the addition of Al_2O_3 fibers and/or particle reinforcement. In particular, the yield strength and the elastic modulus of the hybrid composite were $\sim 88\%$ and $\sim 40\%$ higher than that of the matrix alloy (Fig. 12). However, the ductility was compromised when compared to the unreinforced AM60 matrix alloy. Similarly, the microstructural studies also revealed significant grain refinement due to the hybrid reinforcement addition.

Fig. 12 Microstructure and mechanical properties of AM60 hybrid composites reported by Zhang *et al.* Reproduced from Zhang, X., Zhang, Q., Hu, H., 2014. Tensile behaviour and microstructure of magnesium AM60-based hybrid composite containing Al_2O_3 fibres and particles. Materials Science and Engineering A 607, 269–276. Available at: <https://doi.org/10.1016/j.msea.2014.03.069>.

Table 3 Mechanical properties of AM alloy-based hybrid composites reinforced with Al_2O_3 fibers and AlN or Al_2O_3 nanoparticles

Material	Yield strength (MPa)	Ultimate strength (MPa)	Failure strain (%)	Modulus (GPa)
AM60	81 ± 6	171 ± 8	6.0 ± 1.3	40 ± 4
AM60/ Al_2O_3 fibers	120 ± 5	189 ± 12	2.2 ± 1.7	50 ± 2
AM60/ Al_2O_3 nanoparticles	142 ± 7	192 ± 15	1.6 ± 1.1	54 ± 5
AM60/ Al_2O_3 fibers + nanoparticles	140 ± 14	216 ± 5	3.5 ± 1.2	53 ± 3
AM60/ Al_2O_3 fibers + n-AlN	139 ± 12	210 ± 7	3.6 ± 0.6	51 ± 4

Recently, Zhou *et al.* (Zhou *et al.*, 2017; Zhou *et al.*, 2019a) also devised a squeeze casting variant to develop AM60 based hybrid composites containing Al_2O_3 reinforcements in the form of fibers and particles. Since the aim of this study is to understand the effects of Al_2O_3 particle size, the hybrid composites were fabricated using Al_2O_3 fibers in combination with either micron or nano sized Al_2O_3 particles and the developed hybrid composites were investigated for their microstructure and mechanical properties. While the addition of Al_2O_3 reinforcements in the form of fibers and micron-sized particles considerably increased the ultimate tensile and yield strengths of the matrix alloy, the ductility was reduced substantially (Table 3). However, the addition of nano-sized Al_2O_3 particles (3 vol%) restored the ductility partially for the hybrid composite. Similar observations were also recorded when the nanosized Al_2O_3 particles were replaced by nanosized AlN particles.

Stir Casting and Friction Stir Processing of Magnesium Composites Containing Hybrid Reinforcements

AZ91D alloy based MMC containing boron carbide and graphite particle reinforcement were fabricated using the conventional stir casting method (Aatthisugan *et al.*, 2017). Here, the effects of graphite reinforcement were studied by comparing the mechanical and tribological of AZ91D/ B_4C -Gr hybrid composite with that of the AZ91D matrix alloy and AZ91D/ B_4C composite containing only B_4C particles. While the addition of B_4C particles to AZ91D alloy monotonically increased the wear resistance, hardness and tensile strength, the wear resistance and strength properties were found to degrade upon graphite addition in the case of AZ91D/ B_4C -Gr hybrid composites, although better than the AZ91D matrix alloy (Fig. 13).

Zhou *et al.* (2012) used the ultrasonic cavitation assisted semisolid stirring to fabricate AZ91 based hybrid composites containing different amounts of carbon nanotubes (CNTs) and silicon carbide (SiC) nanoparticles. The developed hybrid composites displayed a refined microstructure and improved mechanical properties due to hybrid reinforcement addition (Fig. 14). In particular, the tensile and yield strengths were significantly improved by ~45% and 55% respectively when the mass ratio between CNT and SiC nanoparticles was maintained as 7:3 (Fig. 15).

Arokiasamy and Anand Ronald (2017, 2018) investigated the influence of friction stir processing (FSP, as illustrated in Fig. 16) on the properties of Mg hybrid composites reinforced with SiC and Al_2O_3 particles. The results of microstructural studies showed appreciable refinement in grain size from 84 to 7 μm due to heterogenous nucleation of primary Mg grains during friction stir processing. With respect to mechanical properties, an improvement in microhardness from 59.3 Hv to 69.7 Hv due to friction stir surface processing was reported. However, the wear rate was found to increase generally for FSP composites (except sample code FSP 2) when compared to as-cast hybrid composites. The processing details and results from this study are listed in Table 4.

Fig. 13 Mechanical and Tribological properties of AZ91D/SiC-Gr hybrid composites. Reproduced from Aatthisugan, I., Razal Rose, A., Selwyn, D., 2017. Jeadurai Mechanical and wear behaviour of AZ91D magnesium matrix hybrid composite reinforced with boron carbide and graphite. Journal of Magnesium and Alloys 93, 493–503. Available at: <https://doi.org/10.1016/j.jma.2016.12.004>.

Sharma *et al.* (2019) also investigated the influence of FSP tool rotation speed on the properties of AZ61/CNT-GNP (graphene nanoparticles) hybrid nanocomposite. The obtained results (Fig. 17) revealed an improvement of 19.72% in microhardness and 77.5% of compressive strength in comparison with the base metal (AZ31 Magnesium alloy), processed with a tool rotational speed of 1400 rpm.

In a similar study, the friction and wear performance of AZ31/n-Al₂O₃ - CNT hybrid composites fabricated using FSP method were investigated in comparison with AZ31 matrix alloy and the composites reinforced with only n- Al₂O₃ or CNT particles (Lu *et al.*, 2013). While all the composite formulations developed in this study displayed better wear resistance compared to AZ31 base alloy, the composite containing only n- Al₂O₃ particles exhibited lower wear rate compared to CNT containing composites, although the frictional coefficient of CNT reinforced composites were larger (Fig. 18). In the case of hybrid composites, a hybrid

effect was reported. For loads larger than 1.95 MPa, the wear of AZ31/0.1Al₂O₃-0.2CNT was considerably lower compared to other composite formulations. Further, it was also reported that the wear mechanism was generally the delamination of mechanically mixed layer at normal loads greater than 1.3 MPa which transforms into abrasive wear when the normal load was lower than 1.3 MPa.

Development of Magnesium Based Composites Using Disintegrated Melt Deposition Followed by Hot Extrusion

Ugandhar *et al.* (Sinha *et al.*, 2006; Ugandhar *et al.*, 2006) used an innovative disintegrated melt deposition (DMD) technique (Fig. 19) to fabricate hybrid Mg composites containing micron sized SiC and Ti particles. The developed composites were investigated for their mechanical and tribological properties in hot-extruded condition. The results of mechanical characterization revealed an increase in the hardness, modulus and yield strength of the composite alongside reduction in the average CTE value (Table 5).

However, the ductility was adversely affected. Further, the results of scratch hardness tests also correlated well with the hardness and elastic hardness i.e. increase with an increase in the weight percent of the reinforcing particulates (Table 5).

The properties of DMD processed Mg/Ti based hybrid composites reinforced with nanoscale Al₂O₃ or Cu particles were also investigated (Sankaranarayanan *et al.*, 2011b; Seetharaman *et al.*, 2012). In this study, the hybrid reinforcement mixture was pre-

Hierarchical magnesium nano-composites for enhanced mechanical response. *Acta Materialia* 58 (18), 6104–6114. Available at: <https://doi.org/10.1016/j.actamat.2010.07.028>.

processed using the solid-state processing technique of ball-milling with an aim of understanding the influence of hybrid reinforcement pre-processing on the microstructure and mechanical properties of bulk Mg hybrid composites. While the microstructural and mechanical analyses showed significant grain refinement and strength properties enhancement due to hybrid reinforcement addition either pre-processed or added directly, the strength enhancement occurred at the expense of ductility when the hybrid reinforcements are added directly (Table 6). On the other hand, the addition of pre-processed hybrid reinforcements resulted in similar/increased ductility. The authors (Sankaranarayanan *et al.*, 2011a) also performed the addition of ball-milled (Ti + Al) composite mixture to DMD processed pure Mg to develop Mg/Ti- Al_3Ti composite with better strength properties. In this study, the direction addition of Al and Ti to Mg resulted in Mg/Ti- $Mg_{17}Al_{12}$ composite with relatively lesser strength and ductility. In all the cases, the difference in properties were primarily attributed to the changes in reinforcement morphology due to ball-milling.

Table 11 Tensile and compressive properties of Hierarchical Mg composites reported by Habibi *et al.*

Materials	Tensile properties			Compressive properties		
	Yield strength (MPa)	Ultimate strength (MPa)	Failure strain (%)	Yield strength (MPa)	Ultimate strength (MPa)	Failure strain (%)

Available at: <https://doi.org/10.1016/j.matdes.2013.02.028>.

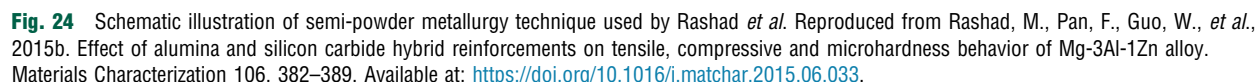

Similar improvements in mechanical properties of Mg/Ti composites were also reported when the Ti particles were hybridized with other nanoscale ceramic and metallic particles such as SiC, B₄C were added (Sankaranarayanan *et al.*, 2013, 2014) (Table 7). Further, the microstructural characterization using EBSD analysis also confirmed more localized recrystallized grains and realignment of basal planes i.e. weak basal fiber texture in the hybrid composites when compared to Mg/Ti (Fig. 20).

Nguyen *et al.* (2011) investigated the effects of Ni particle addition on the performance of AZ31B/1.5 Al₂O₃ nano-composite developed using the method of disintegrated melt deposition (DMD) followed by hot extrusion. It was reported in this study that the addition of 1.5% Ni improved the strength and hardness without significantly affecting the ductility (Table 8). However, the ductility was compromised for AZ31B/1.5 Al₂O₃–3.19Ni. Similar improvement in hardness and strengths were also reported when Cu particles were added to AZ31B/1.5 Al₂O₃ (Nguyen and Gupta, 2010; Nguyen *et al.*, 2012a,b; Nguyen *et al.*, 2012b).

Powder Metallurgy Processing of Magnesium Based Composites Containing Hybrid Reinforcements

Thakur *et al.* (2007a,b) used the microwave assisted powder metallurgy method to develop Mg based hybrid composites. The schematic illustration of the process is shown in Fig. 21. In these studies, the addition of nanoscale reinforcements such as Al₂O₃ and CNT were found to improve the thermal stability and strength properties of Mg/SiC nanocomposites at the expense of ductility (Table 9).

Tun and co-workers (Tun and Gupta, 2009, 2010a,b; Tun *et al.*, 2012, 2013; Fida Hassan *et al.*, 2015a; Fida Hassan *et al.*, 2016; Hassan *et al.*, 2016) also investigated the effects of nanoscale metallic particles addition on the mechanical properties of Mg/Y₂O₃

nanocomposites. The addition of 0.3–1.0 vol% Ni nanoparticles resulted in remarkable increment in the strength properties and tensile ductility due to combined presence of nanosized Y_2O_3 and Mg_2Ni particles (Table 10, Fig. 22). However, the compressive failure strain was adversely affected due to basal plane realignment causing a steep increment in the work hardening attributes and limited failure strain (Tun and Gupta, 2009, 2010a). Recently, the simultaneous addition of Ni and TiO_2 particles was also reported to improve the hardness, tensile and compressive properties of Mg (Olalekan, 2016). Similar results were also reported for nanoscale copper added to Mg/ Al_2O_3 (Tun *et al.*, 2012), Mg/ Y_2O_3 (Tun and Gupta, 2010b; Fida Hassan *et al.*, 2015a; 2016) and Mg/ ZrO_2 (Tun *et al.*, 2013) nanocomposites.

Recently, Habibi *et al.* (Habibi *et al.*, 2010, 2011, 2012a; Habibi *et al.*, 2010, 2011; Habibi *et al.*, 2012b, 2013a,b) also developed Mg based hybrid composites with hierarchical microstructure configurations (i.e., a composite structure within a composite). In these studies, the powders of Al based nanocomposites containing sub-micron or nanosized particulate reinforcements such as Al_2O_3 , Bi_2O_3 , B_4C and CNT were prepared by ball-milling and the composite powder mixture was then used to

prepare Mg based hybrid nanocomposites with a hierarchical configuration as shown in Fig. 23. The mechanical properties of hierarchical composites developed by Habibi *et al.* are listed in Table 11.

Recently, the effects of alumina and silicon carbide hybrid reinforcements on the properties powder metallurgy processed Mg-3Al-1Zn alloy were investigated by Rashad *et al.* (Rashad *et al.*, 2015b). In this study, the processing of Mg-hybrid composites involved blending the matrix and reinforcements particles in a wet medium, followed by the filtration, drying, and compaction of the composite powder blend (as illustrated in Fig. 24). The green composite compact was then sintered and extruded for microstructural and mechanical testing. While the results showed improvement in microhardness and tensile strength of the extruded hybrid composites at the expense of tensile strain with increasing reinforcement content, the tensile fracture strain was found to improve upon heat treatment (Table 12). Similar improvements in mechanical properties were also reported when (copper + graphene nanoplatelets) and (titanium + aluminum) hybrids were added to Mg (Rashad *et al.*, 2015c; Rashad *et al.*, 2015a).

Recently, Zhou *et al.* (Zhou *et al.*, 2019b) used the powder metallurgy method followed by hot extrusion to develop the multi-scaled micron SiC and carbon nanotubes (CNTs) reinforced AZ61 matrix composites as illustrated in Fig. 25. In this study, the

Fig. 29 High magnification SEM micrograph of the 5.5 wt% (TiB_2 – TiC)/AZ91 composite fabricated by adding (TiB_2 + TiC)-Al master alloy with 40 wt% Al. (Ma *et al.*, 2005).

CNTs were properly dispersed onto the surface of micron sized SiC particles and then integrated with AZ80 powders using the ball-milling process. The results of mechanical testing revealed ultra-high strength (~ 400 MPa) and ductility (8%) of AZ61/5SiC-0.5CNT due to the synergistic influence of grain refinement, load transfer and increased dislocation density in the matrix due to thermal mismatch accompanied by a weakened basal texture (Fig. 26, Table 13).

Some of the recent literatures also focussed on the tribological behavior of Mg based hybrid composites containing particle lubricants such as graphite, MoS_2 and CNTs. Narayanasamy and Selvakumar (Narayanasamy and Selvakumar, 2017) investigated the dry sliding wear behavior of powder metallurgy processed Mg composites reinforced with TiC and MoS_2 . While the wear test

results under dry sliding condition showed better wear resistance and reduced coefficient of friction for the hybrid composites due to the formation of a smooth MoS₂-rich tribo-layer, TiC content was found to be beneficial only up to 15%, beyond which the wear loss had the propensity to increase. In a similar study (Turan *et al.*, 2019), a best combination of mechanical and tribological properties were recorded for the AZ91/0.15 wt%CNT-0.15%GNP composite reinforced with multiple carbon-based reinforcements such as CNTs and GNPs (Fig. 28). Similar improvement in wear resistance was also reported in the case of Mg-SiC-Graphite hybrid composites (Soorya Prakash *et al.*, 2016). (Fig. 27).

Development of Mg Hybrid Composites Containing In-Situ Formed Reinforcements

The review of recent literatures also highlights the in-situ synthesis of hybrid (TiB₂ + TiC) reinforcement based on the solid-state chemical reactions between the Ti, B and C phases. Ma *et al.* (2005) and Xiuqing *et al.* (2005) used the self-propagating high temperature synthesis based powder metallurgy technique to prepare a master Al/(TiB₂-TiC) composite which was then re-melted and diluted using the stir casting method to produce AZ91/TiB₂-TiC hybrid composite with improved mechanical properties and wear resistance. The reactions between Ti, Al and B₄C phases were explained as follows:

The developed composites with in-situ ($\text{TiB}_2 + \text{TiC}$) particles (Fig. 29) displayed better mechanical properties (Xiuqing *et al.*, 2005) and wear resistance (Ma *et al.*, 2005) as shown in Table 14.

Sahoo and Panigrahi (Sahoo and Panigrahi, 2016, 2018a,b, 2019a,b; Sahoo *et al.*, 2018) also confirmed the in-situ formation of TiC and TiB_2 phases due to the interaction of Ti , and B_4C powders with molten Mg in $\text{AZ31/Ti-B}_4\text{C}$ composite as shown in Fig. 30. The developed composites were investigated for mechanical properties in terms of yield strength, yield asymmetry and deformation behavior in the as-cast and heat-treated condition, which showed improved ductility under heat-treated condition (Fig. 31 and Table 15).

Concluding Remarks

In this article, the research efforts made thus far on the development of magnesium-based metal matrix composites containing hybrid reinforcements are summarized. The processing techniques adopted so far include melt infiltration, squeeze casting, stir casting, friction stir processing, disintegrated melt deposition and powder metallurgy methods. While hybrid reinforcement additions were originally proposed as an economical alternative to replace only a small quantity of the expensive fiber reinforcement, the improvements in mechanical, creep and tribological properties of Mg alloys due to hybrid reinforcements are found to be comparable to that of the fiber or particle reinforced Mg composites.

In this perspective, a variety of other hybrid reinforcement addition such as the mixture of different length scale particles and the combination of ceramic and metallic reinforcements have been used to develop Mg based hybrid composites and the review of existing literature suggests that the benefits of hybrid reinforcement addition generally depends on the matrix composition, reinforcement morphology, their distribution, and the interfacial integrity between the matrix and reinforcements.

Although in most cases, hybrid reinforcement additions enhance the mechanical, tribological, thermal and impression creep characteristics, corrosion response is often compromised. Similarly, superior improvements in mechanical properties are achieved when a dilute volume fraction of nanoscale ceramic/metallic dispersions are introduced either alone or in combination with other fiber/particle reinforcements when compared to micron scale particles.

The pre-processing of hybrid reinforcements also has a positive influence on the interfacial characteristics and the mechanical properties of Mg -hybrid composites. Similar enhancement in interfacial bonding and mechanical properties are also found in case of Mg hybrid composites containing in-situ formed hybrid reinforcements wherein the chemical reactions between matrix and reinforcements facilitates the formation of multiple reinforcing phases with good interfacial integrity and effective load transfer.

While most hybrid reinforcements results in comparable mechanical properties as that of the matrix material or the composites reinforced with single reinforcement, the best set of mechanical properties (ultra-high tensile strength ($\sim 400 \text{ MPa}$) and moderate ductility (8%)) is reported in the case of CNT and SiC particles reinforced AZ61 composites prepared using the method of powder metallurgy followed by hot extrusion.

The hybrid reinforcement methodology is also considered to be beneficial for industrial/domestic waste recycling as a small amount of the same can effectively be used as functional hybrid reinforcements to develop environment friendly composites.

Metal Based Composites With Metastable/Amorphous Reinforcements

Penchal Reddy Matli and Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introduction

Composite is defined as a judicious combination of two or more different materials to achieve distinctive properties that cannot be achieved by any of its components individually (Rajak *et al.*, 2019). Traditional engineering sectors such as automotive, sports and aerospace are specially looking for lightweight composites (Avedesian and Baker, 1999; Ibrahim *et al.*, 1991; Safri *et al.*, 2018; Surappa, 2003). Presently, the automotive industry manufacturers have started using lightweight composites more aggressively. For most components made of lightweight composites, durability and strength plays a significant role while considering cost savings due to the high cost of fuel and the need to mitigate greenhouse gas emissions. Further, advancement in processing methods has enabled discontinuously reinforced composites to be produced in large scales (Rajan *et al.*, 1998; Ramanathan *et al.*, 2019).

Based on the matrix material, the composites can be categorized as Ceramic Matrix Composites (CMCs), Polymer Matrix Composites (PMCs) and Metal Matrix Composites (MMCs). Among these categories of composites, MMCs exhibit superior combination of mechanical, thermal properties and lightness making them particularly suitable for automobile body parts such as rotors and brake drums (Ekka *et al.*, 2014; Miracle, 2005). Commonly used lightweight metallic matrices, ceramic and amorphous reinforcements are shown in Fig. 1.

By the incorporation of a strong and compatible reinforcement, characteristics of metallic matrix such as stiffness, strength, wear resistance, elastic modulus and corrosion resistance can be enhanced. Al and Mg being the lightest structural metals are most sought after for the production of light-weight structures. Besides being light, Al and Mg based materials also exhibit excellent machinability, good castability, and superior mechanical properties besides being cost effective. As a result, they are also being looked as functional materials in electronic packaging, electricity transmission in addition to automotive/space/aerospace/military and sport sectors (Gupta and Sharon, 2010; Matli *et al.*, 2020; Prabu *et al.*, 2006; Reddy *et al.*, 2019; Zheng *et al.*, 2013). The current and prospective applications of MMCs in various commercial/industrial sectors (Ramanathan *et al.*, 2019) are shown in Fig. 2.

Conventionally, metallic matrices are strengthened by ceramic reinforcements such as titanium oxide (TiO₂), aluminum oxide (Al₂O₃), boron carbide (B₄C), silicon carbide (SiC), aluminum nitride (AlN), and graphite (C) (Meenashisundaram *et al.*, 2015; Reddy *et al.*, 2017a,b; Ubaid *et al.*, 2017; Xiang *et al.*, 2016). Using ceramic based reinforcements, MMCs have attained many of the targeted application driven properties. However, the major limitation of MMCs particularly with micron size reinforcements is their low ductility, which can be attributed primarily due to particle breakage and poor interfacial characteristics (El-Labban *et al.*, 2016; Hwu *et al.*, 1996). While the particle breakage is size dependent, poor interfacial characteristics can be attributed to poor wettability between the matrix and the reinforcement particles. Owing to this drawback, particle agglomeration and interfacial defects occur, which have limited the utilization of MMCs in commercial/industrial applications (Dorward and Pritchett, 1988; Miracle, 2005; Rawal, 2001). As a promising solution to overcome the existing limitations (e.g., low ductility) of MMCs, a new class of reinforcements, namely metallic amorphous alloys was proposed.

Metallic amorphous alloys are a new class of materials that inherently exhibit superior mechanical properties (Inoue, 2001). This is because of their structure (i.e., random or short-range atomic order), and thermal behavior (i.e. the presence of glass transition temperature (T_g) and crystallization temperature (T_x)) (Zhou *et al.*, 2020) as shown in Fig. 3. Due to their unique structure, amorphous alloys deliver large elastic strain limit (~1 to 2%), high hardness and strength (~1–2 GPa) and high corrosion resistance (Inoue, 2001) when compared to the conventional materials. As a result of their high strain limit and high strength, metallic glasses are natural candidates for use as reinforcement especially at micron length scale in metallic matrices.

Since the early 2000s, metallic glass reinforcements have gradually being recognized as promising reinforcements in metallic matrices (Jayalakshmi *et al.*, 2018; Jayalakshmi and Gupta, 2015; Scudino *et al.*, 2008; Yu *et al.*, 2006). Due to their metallic nature, they are easily wetted and exhibit good interfacial bonding with the matrix (Khan *et al.*, 2018). With the use of Al-, Zr-, Fe-, Ni-, Cu- and Mg- based metallic glass particles (Guan *et al.*, 2020; Jayalakshmi *et al.*, 2014; Scudino *et al.*, 2009; Wang *et al.*, 2014b; Yuan *et al.*, 2014; Zhang *et al.*, 2018) as reinforcement, several studies have reported improvement in mechanical properties of metallic matrices.

In this article, emphasis is placed on Al and Mg matrices reinforced with different amorphous metallic particles. Synthesis methods, microstructure and mechanical properties of these composites are presented in forthcoming sections.

Synthesis of Metallic Amorphous Particles

At present, Powder metallurgy stood as the dominant manufacturing technique for the fabrication of industrial parts. In the final quarter of 20th century, PM has a rapid growth due to evolution of novel material processing phenomenons like rapid solidification process (RSP), mechanical alloying (MA) etc., for manufacturing powder. The metallic glasses have broadly manufactured by the mechanical alloying from the above technique.

Fig. 1 Typical light metals and ceramics and amorphous reinforcements used for weight critical MMCs.

Fig. 2 Applications of MMCs in various fields.

Mechanical alloying is one of the powder metallurgy processes that involve repeated cold welding, fracturing, and rewelding of metallic powder particles. Due to solid-state inter diffusion reactions, amorphous structure occurred in mechanical alloying. [Fig. 4](#) represents the transformation of crystalline to amorphous phase using high energy mechanical alloying ([Suryanarayana, 2001](#)).

Fabrication of MMCs With Amorphous Particles

The metal matrix composites require metals in solid and liquid state for their fabrication. There is the possibility of coexistence of solid and liquid forms of the metal in the semi solid process. Till now, all the researchers produced fully amorphous reinforced

Fig. 3 Morphology, XRD pattern and DSC trace of $\text{Fe}_{52}\text{Cr}_{15}\text{Mo}_{26}\text{C}_3\text{B}_1\text{Y}_3$ amorphous powder.

Fig. 4 Schematic diagram representing the transformation of crystalline to amorphous.

Al/Mg matrix composites using solid and liquid metallurgy routes (Jayalakshmi *et al.*, 2018). Some of the most common fabrication methods used by different researchers are described below.

Conventional and Advanced Processing Methods

Squeeze casting infiltration (SCI)

In this process, metal composites were fabricated by the infiltration of a molten alloy in amorphous particle preform, followed by solidification (Lee *et al.*, 2004).

By applying the hydraulic pressure or vacuum, the infiltration of molten metal in the preform was achieved. The production of metal composites by using the casting infiltration has increased gradually. The schematic representation of this process (Ramanathan *et al.*, 2019) is shown in Fig. 5. It was the first report on the synthesis and properties of the novel Al composites containing Ni–Nb–Ta alloy metallic glass particles (Lee *et al.*, 2004).

Compocasting (CS)

In the compocasting technique (Gladston *et al.*, 2017), preheated reinforcement particles are added into semi solid metal at predetermined temperature and dispersed using stirring. The semisolid slurry is poured in a die and solidified. The solidified billet can be further processed using secondary processing techniques (Fig. 6). This method has been shown to be successful in realizing good distribution of reinforcement particles, low porosity and fairly homogeneous and globular microstructure. The low processing temperature and production cycle time enhances the die life significantly and was the main advantages of compocasting.

Blend-compact-sinter method (BCS)

Using this method, metal matrix composites were synthesized by blending the matrix and amorphous reinforcement followed by compaction and sintering. The temperature of sintering is normally controlled so as to retain the amorphous nature of reinforcement. Using this method, composites with high volume percent of reinforcement (> 40%) can be developed. This process was successfully used to develop Al matrix composites containing Zr-based and Ni-based glassy particles (Yu *et al.*, 2006; Scudino *et al.*, 2009).

Fig. 5 Schematic diagram of squeeze casting infiltration method.

Fig. 6 Schematic diagram showing different steps in compocasting.

Powder metallurgy accompanied with microwave sintering (MWS)

This method is similar to traditional powder metallurgy method except that it employs microwave sintering. In microwave sintering, the heat is produced within the materials by microwaves, which radiates out after heating samples unlike in conventional sintering. To reduce the problem of variable heating the bi-directional hybrid microwave sintering was developed. Experimental setup (Gupta and Eugene, 2011) used for bi-directional hybrid microwave sintering is shown in Fig. 7. The SiC susceptors transmits the heat to billets from outside and microwaves absorbed by billets heats the billet from inside-out. This type of bi-directional heating ensures removal of thermal gradient, which automatically ensures a uniform heating of billets. The bi-directional microwave sintering technique assists in reducing sintering time and good integration between reinforcement and matrix. As the microwave sintering can be realized in relatively shorter period of time, undesirable reactions at the matrix/reinforcement interface can be minimized or prevented.

In disparity, in the view of conventional sintering a long sintering period is required that arise to non-beneficial reactions. Jayalakshmi *et al.* (2014) developed magnesium based metal matrix composites containing $\text{Ni}_{60}\text{Nb}_{40}$ metallic glass reinforcement particles using microwave sintering followed by extrusion.

Powder metallurgy accompanied with spark plasma sintering (SPS)

This method is similar to traditional powder metallurgy method except that it employs spark plasma sintering in place of conventional sintering. Spark plasma sintering (SPS) can be conducted in a short period of time and can ensure minimal grain growth. The simplified set up of the process (Zhang *et al.*, 2014) is presented in Fig. 8.

Fig. 7 Schematic setup for bi-directional hybrid microwave sintering.

Fig. 8 Experimental setup for spark plasma sintering process.

In SPS sintering, the contribution of Joule heating effect in densification assists in compacting powders to near theoretical density. In SPS, the high heat rate (up to ~ 1000 K/min) which is generated internally is same as microwave sintering. $\text{Fe}_{50}\text{Cr}_{25}\text{Mo}_9\text{C}_{13}\text{B}_3$ metallic glass particles reinforced aluminum composites were successfully synthesized by spark plasma sintering assisted PM method (Guan *et al.*, 2020).

Powder metallurgy accompanied with high frequency induction heat sintering (HFIHS)

High frequency induction heat sintering (HFIHS) is a sintering technique in which metal and reinforcement are sintered rapidly (Khalil and Almajid, 2012). In order to heat the samples, an intense magnetic field is applied by an electrically conducting pressure die, during the operation of unit. Utilizing high temperature and pressure, the metallic powders can be quickly sintered in a short period of time. Grain growth does not occur in the sintered samples due to the high heating and cooling rates involved. Aljerf *et al.* (2012) produced $[(\text{Fe}_{0.5}\text{Co}_{0.5})_{75}\text{B}_{20}\text{Si}_5]_{96}\text{Nb}_4$ metallic glassy particles reinforced Al composites by the HFIHS process.

Accumulative roll bonding (ARB)

Accumulative roll bonding (ARB) process to synthesize MMCs is shown in Fig. 9 (Saito *et al.*, 1999). ARB technique comprises of stacking of two sheets of same material with reinforcement particles in between the sheets (Ramanathan *et al.*, 2019).

The process is often repeated and heat treatment in between is normally involved. In ARB much emphasis is placed to clean the mating surfaces thoroughly to ensure good bonding between them. Choosing an appropriate temperature is one of the most

Fig. 9 Schematic of the ARB process.

important parameter in this technique. It should be less than recrystallization temperature of the amorphous reinforcement and at the same time should be able to ensure good bond strength between the sheets and particles. Khoramkhorshid *et al.* (2016) prepared $\text{Al}_{84}\text{Gd}_6\text{Ni}_7\text{Co}_3$ glassy particles reinforced Al composites by accumulative roll bonding (ARB) which exhibited excellent mechanical properties.

Friction stir processing (FSP)

Friction stir processing is an advanced version of friction stir welding, through which the surface composites can be fabricated conveniently (Wegłowski and Pietras, 2011). The rotating tool having shoulder and pin is kept in contact with the work piece continuously along the length and breadth of the surface. To fabricate a composite on metal surface, gaps are made which are filled with reinforcement powder later. A rapid plastic deformation and mixing of materials is obtained by the heat provided through friction generated when the FSP tool is passed through the gaps filled with reinforcement powders. An efficient enhancement was realized in the properties such as increased hardness, resistance to wear and corrosion fatigue in the materials that are modified by FSP. Magnesium matrix composites containing amorphous SiO_2 particles were fabricated through friction stir processing (Lee *et al.*, 2006).

Microstructure and Mechanical Properties of Al-based MMCs

Rezaei *et al.* (2016) produced aluminum based composites with $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ metallic glass reinforcement particles using equal channel angular pressing (ECAP) technique. In this process, mechanical alloying was used to prepare $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ metallic glass particles. In order to fabricate fully glass $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ particles, the ball milling was continuously repeated for 30 h. XRD patterns of the ball milled $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ glassy powder, pure Al and Al/AMG composites with varying reinforcement particles (5, 10 and 15 vol%) are shown in Fig. 10. The X-ray diffractogram of blended $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ powders showed a wide hump at $35^\circ \leq 2\theta \leq 50^\circ$, without the presence of any characteristic peaks representing an amorphous phase. Al/10vol% AMG composite exhibited 52% increase in yield strength when compared to pure Al.

Wang *et al.* (2014a) fabricated Al-based metallic glass ($\text{Al}_{84}\text{Gd}_6\text{Ni}_7\text{Co}_3$) particles reinforced Al matrix composites by powder metallurgy through hot pressing followed by hot extrusion. The authors reported that $\text{Al}_{84}\text{Gd}_6\text{Ni}_7\text{Co}_3$ reinforcement particles were distributed uniformly within the Al matrix with good metallurgical bonds. Also, they observed ~63% and 69% improvement in yield strength and ultimate tensile strength for the composite with 20 vol% of $\text{Al}_{84}\text{Gd}_6\text{Ni}_7\text{Co}_3$ reinforcement.

Balci *et al.* (2015) investigated 40 vol% of $\text{Fe}_{50.1}\text{Co}_{35.1}\text{Nb}_{7.7}\text{B}_{4.3}\text{Si}_{2.8}$ glassy particles reinforced Al composites processed through powder metallurgy and consolidation process. A detailed study of microstructure and mechanical properties was conducted. The SEM micrographs of extruded Al composites at different milling times are shown in Fig. 11. The hot extrusion was responsible for improvement in density and the absence of pores in SEM micrographs of the composite sample. The composite attained high strength (390 MPa) and remarkable plasticity (21%).

Fig. 10 (a) X-ray diffraction patterns of Al- $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ composites and (b) the enlarged figure showing broadening (220) and (311) peaks for the composites.

Fig. 11 SEM micrographs of Al-40 vol% $\text{Fe}_{50.1}\text{Co}_{35.1}\text{Nb}_{7.7}\text{B}_{4.3}\text{Si}_{2.8}$ composites at different milling times (a) 1 h, (b) 10 h, (c) 30 h and (d) 50 h.

Yuan *et al.* (2014) incorporated high volume percentage (40% and 60%) of Al-based ($\text{Al}_{60}\text{Cu}_{20}\text{Ti}_{15}\text{Zr}_5$) glassy alloy particles in pure Al matrix by using hot pressing method. In this investigation, Al-based ($\text{Al}_{60}\text{Cu}_{20}\text{Ti}_{15}\text{Zr}_5$) glassy alloy particles were successfully obtained after 120 h of ball milling.

The influence of the consolidation temperature on the structural and compression behavior of the composites was studied. At a temperature of 390°C , the densification values for 40 vol% Al and 60 vol% Al were found to be 91% and 96% respectively. They found that the Al-40 vol% $\text{Al}_{60}\text{Cu}_{20}\text{Ti}_{15}\text{Zr}_5$ composite consolidated at 390°C exhibited maximum yield strength and ultimate strength of 307 MPa and 353 MPa, respectively.

Guan *et al.* (2020) studied Al- $\text{Fe}_{50}\text{Cr}_{25}\text{Mo}_9\text{C}_{13}\text{B}_3$ composites developed using SPS technique and hot rolling method. They reported that shell structure had a unique effect on microstructure and compression behavior of the composites. The uniform

Fig. 12 (a)–(d) FESEM images of Al composites reinforced with FMG particles (10, 20, 30 and 40 vol%) and (e) higher magnification micrograph. The results of EDX mapping images (lower part) of the composite containing 40 vol% FMG particles.

distribution of the spherical Fe-based metallic glass FMG particles in the Al matrix is shown in **Fig. 12(a)–(d)**. **Fig. 12(e)** shows a high magnification micrograph of the composite containing 40 vol% of FMG particles.

The FMG particles resemble a concentric ring having a lot of uneven protrusions at the edge of the ring through which the surface of the FMG core was covered. The FMG core contained Fe, Cr and Mo.

[Jayalakshmi et al. \(2014\)](#) studied that the properties of the amorphous $\text{Ni}_{60}\text{Nb}_{40}$ alloy powders reinforced Al-based composites through bi-metallic microwave sintering technology which follows hot extrusion. The rapid improvement of mechanical properties of the Al- $\text{Ni}_{60}\text{Nb}_{40}$ composites has been attained by the amorphous reinforcement was concluded by the authors. When compared to pure Al, the compressive yield strength of the developed composite has increased from 40% to 100% with the increasing vol% of the reinforcement ($\text{Ni}_{60}\text{Nb}_{40}$).

[Zhang et al. \(2018\)](#) showed that CuZrAl metallic glass particles can be synthesized by mechanical alloying method. Sintering technique was employed to fabricate different volume fractions of CuZrAl particles reinforced Al-based composites. The microstructure and mechanical properties of the aluminum based composites were studied. The composite with 20 vol% CuZrAl reinforcement exhibited superior microhardness, yield strength and fracture strength of 290 HV, 408 MPa and 459 MPa, respectively. The enhancement in mechanical properties was attributed to the second phase strengthening, good interface, and grain refinement.

[Wang et al. \(2014b\)](#) developed $\text{Mg}_{58}\text{Cu}_{28.5}\text{Gd}_{11}\text{Ag}_{2.5}$ glassy particles reinforced Al matrix composites by powder metallurgy including hot pressing. They reported fairly uniform distribution of $\text{Mg}_{58}\text{Cu}_{28.5}\text{Gd}_{11}\text{Ag}_{2.5}$ glassy particles in the Al matrix. An enhancement in significant strength was reported primarily attributed to good reinforcement matrix interface.

[Zhou et al. \(2020\)](#) fabricated Al based composites containing $\text{Fe}_{52}\text{Cr}_{15}\text{Mo}_{26}\text{C}_3\text{B}_1\text{Y}_3$ amorphous particle using powder metallurgy technique. They reported the formation of near dense composites with uniform distribution of reinforcing particles. They reported tensile strength of 234 MPa for 20 vol% of Fe-metallic glass particles, which was 154% higher than that of pure Al. Besides, hardness was improved from 46 HV to 220 HV. The fracture mechanism of the composite was mostly mixed mode showing evidences of brittle and ductile fracture features.

Fig. 13 TEM micrograph of Al-Ni₇₀Nb₃₀ composite.

Fig. 14 The bulk density and porosity content of Al-Fe₅₂Cr₁₅Mo₂₆C₃B₁Y₃ composites.

Al-Ni₇₀Nb₃₀ amorphous composite through powder metallurgy technique was fabricated by [Yu et al. \(2006\)](#). The sintering temperature less than the melting point of Al (730 K) have been employed in the fabrication of the composite. [Fig. 13](#) represents the transmission electron microscopy (TEM) of the sintered sample, that explains a proper bond was formed in between Ni₇₀Nb₃₀ with the Al matrix, pore-free matrix and absence of any reaction zones.

[Rezaei et al. \(2020\)](#) prepared Fe-based metallic glass (FMG) reinforced novel Al composite through spark plasma sintering (SPS) method. The physical and mechanical characteristics of composite materials were investigated. They reported the retention of amorphous structure of the FMG reinforcement and absence of interfacial reactions in the consolidated Al-Fe₅₂Cr₁₅Mo₂₆C₃B₁Y₃ composites.

The difference in the bulk density and porosity of the composite samples is represented in [Fig. 14](#). The composite samples exhibited higher porosity when compared to pure Al. The bulk densities of all the samples were found to be almost equal irrespective of the presence of FMG particles.

To understand the magnitude of strength with addition of CNTs in Al, the tensile test results of CNT-reinforced pure Al and Al2024 are shown in [Fig. 12\(a\)](#) and [\(b\)](#), respectively.

[Zhang et al. \(2018\)](#) by using SPS phenomenon, Different amounts of (in vol%) of CuZrAl metallic amorphous particles have been reinforced into Al matrix. The mechanical properties of the SPSed composites have been noted. From [Fig. 15](#), It can be observed that with the increasing of vol% of CuZrAl, the microhardness of the composite have gradually enhanced. At 20 vol% of CuZrAl, the microhardness was found to be maximum enhancement, thereafter hardness showed a declining trend.

Fig. 15 Microhardness of the SPS processed pure Al and Al-CuZrAl composites.

Fig. 16 True stress-true strain curves of (a) Al-Al₆₅Cu₂₀Ti₁₅ composites, (b) Al-Mg₅₈Cu_{28.5}Gd₁₁Ag_{2.5} composites, (c) Compression properties of Al-Ni₆₀Nb₄₀ composites, and (d) SPS-ed Al-CuZrAl composites.

To understand the magnitude of compressive strength with addition of amorphous particles in Al matrix, the compression test results of Al₆₅Cu₂₀Ti₁₅, Mg₅₈Cu_{28.5}Gd₁₁Ag_{2.5}, Ni₆₀Nb₄₀ and CuZrAl glassy particles reinforced Al based composites are shown in Fig. 16(a)–(d), respectively. The strength of the Al composites increases with the increasing amount of AMG reinforcement up to 10 vol% and hereafter a decrease in strength and ductility for Al/15 vol% AMG composite can be observed in Fig. 16(a). With the addition of glass reinforcement, the mechanical behavior of the Al matrix was enhanced significantly.

Fig. 17 Tensile properties of (a) Al-Ni₆₀Nb₄₀ composites, (b) Al-20 vol% Al₈₄Gd₆Ni₇Co₃ particles, and (c) tensile true stress-strain curves of the Al composites reinforced with Fe₅₀Cr₂₅Mo₉C₁₃B₃ metallic glass particles.

The strength of the Al composites increases with the increasing amount of AMG reinforcement up to 10vol% and hereafter a decrease in strength and ductility for Al/15 vol% AMG composite can be observed in Fig. 16(a). The compression stress-strain plots of Al-Mg₅₈Cu_{28.5}Gd₁₁Ag_{2.5} composite are presented in Fig. 16(b). With the addition of glass reinforcement, the mechanical behavior of the Al matrix was enhanced significantly. Considering 30 vol% glass-reinforced Al composite, the yield and compressive strength was improved by 38% and 35%, respectively. The representative stress-strain curves for hot extruded Al-Ni₆₀Nb₄₀ reinforced composites under compression loading are shown in Fig. 16(c). A significant enhancement in yield strength was realized due to the presence of amorphous reinforcement in the developed composites. The hot extruded composite showed about 45%–100% strength improvement with increase in volume fraction of Ni₆₀Nb₄₀ amorphous alloy particles. Compression property measurements of the SPS processed Al composites containing CuZrAl metallic glass particles are shown in Fig. 16(d). High yield strength ($\sigma_{0.2}$) and fracture strength (σ_f) was observed for spark plasma sintered Al-CuZrAl composites when compared to SPS processed pure Al. Al-20 vol% CuZrAl composites exhibited yield strength of 408 MPa which is improved by 946% when compared to pure Al (39 MPa). However, the compressive ductility of 20 vol% and 30 vol% of CuZrAl particles containing composites was marginally affected and stands at about 18% and 20%, respectively.

Fig. 17 shows the room temperature stress-strain curves for various amorphous particles reinforced Al composite samples under tensile loading. Fig. 17(a) shows the tensile stress-strain curves for the Al-Ni₆₀Nb₄₀ composites. The study revealed that a critical volume fraction (5%) of Ni₆₀Nb₄₀ reinforcement is required for improving the strength of aluminum. Ultimate tensile strength of Al-25vol% Ni₆₀Nb₄₀ composite was best and improved by ~60%. Fig. 17(b) shows a typical room temperature tensile stress-strain curve for the 20 vol% Al₈₄Gd₆Ni₇Co₃ particles reinforced Al matrix composite together with a curve for the unreinforced extruded pure Al. The yield strength and ultimate tensile strength of pure Al increased from 75 MPa and 93 MPa to 120 MPa and 157 MPa for Al-20 vol% due to the presence of Al₈₄Gd₆Ni₇Co₃ reinforcement. Room-temperature stress-strain curves of Al-Fe₅₀Cr₂₅Mo₉C₁₃B₃ composites are shown in Fig. 17(c). The ultimate tensile strength increases from 157 ± 6 MPa for pure Al to 212 ± 5 , 224 ± 4 , 239 ± 4 and 254 ± 5 MPa for the composites reinforced with 10, 20, 30 and 40 vol% FMG particles, respectively. For 40 vol% of FMG particles, there was an enhancement of about 60% in ultimate strength but the ductility was reduced to 9.3%. Ultimate tensile strength of Al-40 vol% Fe_{50.1}Co_{35.1}Nb_{7.7}B_{4.3}Si_{2.8} composite was found to be higher than

the Al-40 vol% $\text{Fe}_{74}\text{Mo}_4\text{P}_{10}\text{C}_{7.5}\text{B}_{2.5}\text{Si}_{2.8}$ metallic glass composite (Zheng *et al.*, 2013). Al composite reinforced with core-shell structured FMG particles exhibited superior mechanical properties due the strong interfacial bonding (Miracle, 2005).

Table 1 summarizes the mechanical properties of Al matrix composites with various groups of amorphous reinforcement. It can be observed that Al-25 vol% $\text{Ni}_{60}\text{Nb}_{40}$ composite exhibited highest combination of yield strength and ultimate compressive strength at 155 MPa and 375 MPa, respectively. According to **Table 1**, the Al-40 vol% $\text{Fe}_{50.1}\text{Co}_{35.1}\text{Nb}_{7.7}\text{B}_{4.3}\text{Si}_{2.8}$ composite sample showed the maximum yield (340 MPa) and ultimate tensile strength (470 MPa). From the **Table 1** we can conclude that Fe-based glassy particles are one of the most potential replacements for the conventional ceramic or other metallic glass reinforcements.

Microstructure and Mechanical Properties of Mg-Based MMCs

In comparison to ceramic reinforcements, the metallic reinforcements have unique advantage of improving the interface compatibility with metal matrix. Jayalakshmi *et al.* (2014) developed Mg- $\text{Ni}_{60}\text{Nb}_{40}$ composites by PM method involving microwave sintering and hot extrusion. In this investigation, $\text{Ni}_{60}\text{Nb}_{40}$ (at%) amorphous alloy powder was prepared through mechanically alloying. XRD pattern of the ball milled $\text{Ni}_{60}\text{Nb}_{40}$ powder is shown in **Fig. 18(a)**. By successively ball milling of powders for 87 h, the amorphous characteristics in XRD studies were observed (a hump rather than sharp peaks). Thermal properties of the amorphous powders are shown in **Fig. 18(b)**. The onset and peak temperatures for crystallization $T_{x\text{-onset}}$ and $T_{x\text{-peak}}$ were observed at 605°C and 657°C, respectively. **Fig. 18(c)** represents FESEM image of $\text{Ni}_{60}\text{Nb}_{40}$ amorphous alloy powders with almost spherical morphology.

Fig. 19 shows the optical micrographs of extruded Mg- $\text{Ni}_{60}\text{Nb}_{40}$ composites. The values of the grain size obtained were found to be within the limits of the standard deviation which means the values are almost similar. When compared to pure Mg the matrix microstructure of all the composites possess fine grains. They concluded that the grain size was declined 2–3 times with respect to the pure Mg.

Sankaranarayanan *et al.* (2015b) fabricated $\text{Ni}_{50}\text{Ti}_{50}$ amorphous particles (3, 6 and 10 vol%) reinforced Mg-composites using microwave assisted rapid sintering and hot extrusion. Microstructural and mechanical behavior of the hot extruded composites were examined. XRD patterns of pure Mg and its composites are shown in **Fig. 20**. Prominent Mg-crystalline peaks and amorphous halo was observed in all the composites. To note that the amorphous halo at the diffraction angle $2\theta = 40^\circ$ was clearly observed in composite samples. By using microwave assisted powder metallurgy method, the novel glassy metallic particles can be incorporated into magnesium matrix successfully as confirmed by these observations. The distribution of $\text{Ni}_{50}\text{Ti}_{50}$ amorphous particles in the Mg matrix is presented in **Fig. 21(a)–(d)**. It reveals that the amorphous particles are distributed fairly uniformly in the matrix with good interface bonding.

Fig. 22(a) and **(b)** displays the ambient temperature stress–strain curves for the Mg- $\text{Ni}_{60}\text{Nb}_{40}$ and Mg- $\text{Ni}_{50}\text{Ti}_{50}$ composites under compression loading. From **Fig. 22(a)**, it can be observed that the strength of the composites increased due to the presence of

Fig. 18 (a) XRD pattern (b) DSC curve and (c) FESEM image of $\text{Ni}_{60}\text{Nb}_{40}$ amorphous alloy powder.

Fig. 19 (a)-(d) Optical micrographs of extruded $\text{Mg-Ni}_{60}\text{Nb}_{40}$ composites.

Fig. 20 X-ray diffractograms of the developed Mg-NiTi composites.

Fig. 21 (a)-(d) SEM micrographs of Mg-Ni₅₀Ti₅₀ composites.

Ni₆₀Nb₄₀. The compressive yield and ultimate strength of the Mg composite at 3 vol% increased by about ~20% where as at 5 vol% an improvement of about ~85% in yield strength and ~30% of ultimate strength was observed. The improvement in mechanical properties can be attributed the uniform distribution of Ni₆₀Nb₄₀ particles, Mg crystal orientation, effect of volume fraction and influence of amorphous reinforcements in matrix strengthening.

From the test results (**Fig. 22(b)**), the Ni₅₀Ti₅₀ amorphous particle reinforced Mg composites showed comparatively better improvement in both the compressive yield (CYS) and ultimate strength (UCS) with minimal variation in compressive ductility. For 3 vol% Ni₅₀Ti₅₀ particle addition, the CYS and UCS increased by ~15% and ~25%, respectively. For Mg-10 vol% Ni₅₀Ti₅₀ composite CYS and UCS increased by ~79% and ~71%, respectively. The results clearly validated that strengths of metallic matrix can be increased by the addition of amorphous Ni₅₀Ti₅₀ particles.

Fig. 22 Engineering stress–strain curves of (a) Mg–Ni₆₀Nb₄₀ and (b) Mg–Ni₅₀Ti₅₀ composites under compressive loading.

Table 2 Summary of research on Mg metal matrix composites (Mg–MMCs) reinforced by amorphous particles

Matrix + reinforcement	Processing techniques	Hardness (HV)	Compressive			Tensile			Reference
			YS (MPa)	UCS (MPa)	FS (%)	YS (MPa)	UTS (MPa)	EI (%)	
Mg-3 vol% Ni ₆₀ Nb ₄₀	Microwave Sintering + Hot Extrusion (PM)	62	85	283	17.6	–	–	–	Jayalakshmi <i>et al.</i> (2014)
Mg-5 vol% Ni ₆₀ Nb ₄₀		84	130	320	18.4	–	–	–	
Mg-10 vol% Ni ₆₀ Nb ₄₀		95	90	322	17.2	–	–	–	
Mg-3 vol% Ni ₅₀ Ti ₅₀	Microwave Sintering + Hot Extrusion (PM)	49	67	291	15.9	94	144	8.8	Sankaranarayanan <i>et al.</i> (2015b)
Mg-6 vol% Ni ₅₀ Ti ₅₀		62	89	368	15.1	127	183	6.5	
Mg-10 vol% Ni ₅₀ Ti ₅₀		66	102	417	14.9	148	178	2.0	
Mg-10 wt% Cu ₅₀ Ti ₅₀	Microwave Sintering + Hot Extrusion (PM)	63	93	403	17.5	–	–	–	Sankaranarayanan <i>et al.</i> (2015a)

Sankaranarayanan *et al.* (2015a) studied the copper-titanium based (Cu₅₀Ti₅₀) amorphous alloy particles reinforced Mg metal matrix using bi-directional microwave sintering process followed by hot extrusion. Authors reported that Cu₅₀Ti₅₀ amorphous alloy particles were distributed uniformly in Mg matrix without any interfacial reactions. The average hardness of the pure Mg was enhanced by ~25% with the addition of Cu₅₀Ti₅₀ amorphous reinforcement. The results of compressive properties of extruded pure Mg and Mg-10 wt% Cu₅₀Ti₅₀ composite are listed in Table 2. When compared to monolithic Mg, the yield and compressive strength of the Mg-10 wt% Cu₅₀Ti₅₀ composite improved by ~40% and ~45%, respectively. The results validated that addition of amorphous Cu₅₀Ti₅₀ particles enhanced strength properties of the Mg due to their high load bearing capacity (Gupta and Eugene, 2011).

Fig. 23 shows the room temperature tensile stress–strain curves of the extruded Mg–Ni₅₀Ti₅₀ composites. Significant improvement in tensile yield strength (TYS) and ultimate tensile strength (UTS) of Mg composites can be seen. The tensile yield and ultimate tensile strength increases from 75 MPa and 119 MPa to 148 MPa and 178 MPa for the Mg composite containing 10 vol% Ni₅₀Ti₅₀ particles. The developed Mg–10 vol% Ni₅₀Ti₅₀ composite exhibited an improvement of 98% in TYS and 50% in UTS, respectively. With the increasing volume percent of amorphous particle addition the tensile strength increased while ductility reduced progressively.

The research work reported in open literature reveals that the metallic glass reinforced Mg composites showed superior mechanical strength properties. The effects of processing method and volume fraction of amorphous reinforcements on the microhardness and strength (compressive/tensile strength) of the composites are presented in Table 2. From the table, it can be seen that the highest compression/tensile strength values are observed in Mg- 10 vol% Ni₅₀Ti₅₀ composite synthesized using microwave sintering followed by hot extrusion.

Current and Future Applications

In the aerospace and automotive industries, the reinforcements at micro/nano length scales in metallic matrices can lead to significant enhancement in properties. The applications of these materials can be targeted for small engines and electronic packing

Fig. 23 Tensile engineering stress-strain curves for Mg-Ni₅₀Ti₅₀ composites.

applications as an example. The results have clearly validated that for metal matrix composites containing amorphous alloy particles, the strength of Al and Mg based composite can be clearly enhanced with comparatively much lower compromise in ductility (compared to ceramic reinforcements in micron length scale) which is required for strength based designs that traditionally follow bend-than-break philosophy. Further, the applicability of amorphous reinforcements in Al and Mg matrices makes them suitable candidates for weight critical applications such as in automotive, aerospace, space, electronics and defense industries. To note that amorphous alloy particles reinforced metal matrix composites can be designed to exhibit low density, high strength, high thermal conductivity and matching coefficient of thermal expansion, making them ideal candidate for such applications.

Summary

From the current understanding on composites containing amorphous particle reinforcement it can be concluded that various fabrication methods can be used for the manufacturing of such composites. Some of the key findings made on these composites are listed below.

- (1) Among the solid-based methods, bi-directional microwave sintering and spark plasma sintering appears to be the most promising techniques for the synthesis of MMCs with superior properties when compared to conventional methods.
- (2) Compared to ceramic reinforcement particles, Al-, Fe-, Ni-, Cu-, and Mg-based metallic glasses can be successfully employed to realize better mechanical properties particularly strength and hardness.
- (3) In improving the mechanical properties of the Al metal matrix containing Fe₅₀Cr₂₅Mo₉C₁₃B₃ metallic glass (FMG) particles, the core shell morphology plays a prominent role.
- (4) The Mg matrix grain size is decreased significantly and hardness is increased by the addition of Ni₅₀Ti₅₀ amorphous reinforcement.
- (5) The average hardness of 206 HV was observed for Al-15 vol% Fe₅₂Cr₁₅Mo₂₆C₃B₁Y₃ composite.
- (6) Al composites containing 25 vol% of Ni₆₀Nb₄₀ and 40 vol% of Fe_{50.1}Co_{35.1}Nb_{7.7}B_{4.3}Si_{2.8} amorphous reinforcement exhibited the highest ultimate compressive strength and ultimate tensile strength of 375 MPa and 470 MPa, respectively.
- (7) Mg composites containing 6 vol% and 10 vol% of Ni₅₀Ti₅₀ amorphous alloy particles exhibited the maximum ultimate tensile/compressive strength of 183 MPa and 417 MPa, respectively.
- (8) Amorphous particles reinforced metal matrix composites demonstrate good mechanical properties that are well suited to many industrial applications.

Introduction

Development of lightweight materials is of great interest for weight-sensitive applications such as automotive, defense and aerospace industries. Light metals offer high specific strength properties and thus provide energy and fuel efficiency. Amongst the existing light metals such as titanium (Ti), aluminum (Al) and magnesium (Mg), aluminum (Al) is attractive due to its low density, high ductility, malleability, good conductivity, high specific strength and its abundant availability (8% of earth crust is aluminum). Aluminum can be reinforced with suitable reinforcement to improve its properties such as high strength to weight ratio, low coefficients of thermal expansion, good wear properties, excellent corrosion resistance and good ductility when compared to the conventional aluminum alloys. Aluminum metal matrix composites are increasingly being used for car parts that are exposed to high loads, such as e.g., piston, brake disks, engine cylinders, drum brakes, push rods, cam gears and others (Babalola *et al.*, 2014; El-Labban *et al.*, 2014; Jiang *et al.*, 2014; Wahyuni *et al.*, 2019).

The tempting properties of Al-based composites make them attractive for a wide variety of commercial/industrial applications (Hatch, 1984; Polmear, 1995). Despite the fact, that Al-based composites have attractive properties, however, their structural, thermal-mechanical, and electrical properties are essentially required to be further modified to address the more demanding future challenges and applications. Usually, Al metal matrix composites (AMMCs) are fabricated by the incorporation of stronger/stiffer and thermally stable non-metallic/ceramic reinforcements (Al_2O_3 , SiC, TiC BN, AlN etc.) into the aluminum matrix to achieve enhanced performance (Pradhan *et al.*, 2015; Reddy *et al.*, 2017a,b; Reddy *et al.*, 2018a,b). The salient features of AMMCs when compared to Al alloys are short-listed below (Surappa, 2003; Stojanović and Ivanović 2015):

- Higher stiffness and strength
- Lower density (weight)
- Controllable thermal properties (heat control/management)
- Improved vibration damping capability
- Enhanced mechanical properties
- Improved stiffness
- Great strength
- Enhanced electrical performance
- Improved abrasion and wear resistance
- Improved high temperature properties

Given the fact that AMMCs can provide superior performance in contrast to their unreinforced alloys, they have found their role as structural and functional materials in advanced applications such as electronic packaging and space/aerospace industries, in addition to being well-utilized in automotive industries, military armory and sporting goods. The current and prospective applications of AMMCs in various commercial/industrial sectors have been shown in Fig. 1 (Lloyd, 1994; Rawal, 2001; Miracle, 2005).

The major limitation of AMMCs in expending their utilization is their low ductility, which is due to the poor interfacial characteristics. This occurs because of the low wettability between the matrix and the reinforcement particles. As a promising solution to overcome the existing limitation (i.e., low ductility) of AMMCs (with conventional ceramic reinforcements), we propose to employ a new class of reinforcements, namely metallic amorphous alloys (AAs)/bulk metallic glasses (BMGs), as a better alternative for the conventional reinforcements. Amorphous metallic alloys or metallic glasses are relative newcomers to the world of glasses, and they have properties that are unusual for metallic solids. Metallic glasses, which exist in a very wide variety of compositions, combine fundamental interest with practical applications. In order to understand the concept of amorphous metallic alloys let us consider Fig. 2 in which crystalline and amorphous structures are presented. In a crystal (below left), there is a great deal of regularity or order to the atomic positions. In comparison, the atomic positions in a glass (below right) are much more disordered. In the crystal, the local environment around each atom is the same, whereas, in the glass, each atom has about six neighbors on average, but some atoms have fewer than six while others have more.

From the last two decades, metallic amorphous alloys (AAs)/bulk metallic glasses (BMGs) are a new class of materials that inherently have superior mechanical properties. This is because of the fact that these are distinctly different from conventional metals in terms of their structure (i.e., the sense of long-range atomic order), metastable thermal behavior (i.e., the presence of glass transition temperature (T_g)), and crystallization temperature (T_x) as shown in Figs. 3 and 4.

Fig. 1 Some industrial aluminum metal matrix composites.

Fig. 2 Different degrees of ordered structures: crystal (left) and amorphous (right). Reproduced from Zallen, R., 2008. The physics of amorphous solids. John Wiley & Sons.

With this unique structure, amorphous alloys exhibit high strength ($\sim 1\text{--}2$ GPa), large elastic strain limit ($\sim 1\%\text{--}2\%$) and high corrosion resistance when compared to the conventional materials (Luborsky, 1983; Telford, 2004; Sheng *et al.*, 2006; Dąbrowa *et al.*, 2015; Jayalakshmi and Gupta, 2015). Moreover, due to their high strain limit and high strength, metallic glass is a natural candidate for use as a reinforcement in composite materials.

There have been a large number of attempts to develop composites with amorphous reinforcements. Issa *et al.* (2017) reported the fabrication and mechanical properties of aluminum/amorphous SiO_2 nanocomposites with different weight percent of SiO_2 (0–3.0 wt%) using powder metallurgy and hot extrusion techniques. The SiO_2 nanoparticles were not visible in the micrographs because of their small size and low in content. It is reported that the addition of 1.0 wt% amorphous silica nanoparticle to Al, has resulted in the improvement of tensile strength and hardness by $\sim 25\%$ and 42% respectively. Jayalakshmi *et al.* (2013) made an attempt to improve the mechanical strength of pure aluminum by the presence of $\text{Ni}_{60}\text{Nb}_{40}$ amorphous alloy powder. $\text{Ni}_{60}\text{Nb}_{40}$ (5, 15 and 25 vol%) was reinforced into aluminum matrix, and the composites were prepared using a novel microwave-assisted rapid sintering technique, followed by a hot extrusion process. It is reported that the hardness and compressive strength values increase with an increasing amount of $\text{Ni}_{60}\text{Nb}_{40}$ reinforcement. The highest concentration of reinforcement (25%) resulted in a significant increase in strength ($\sim 60\%$) due to efficient load transfer and matrix strengthening phenomenon. Lee *et al.* (2004) reported the fabrication and mechanical properties of Ni-Nb-Ta (Ni–20.6 Nb–40.2Ta) amorphous alloy ribbons reinforced aluminum composites prepared by the infiltration casting process. It is reported that the Ni–20.6 Nb–40.2Ta metallic glass ribbons were uniformly distributed in the Al matrix. It was observed that the addition of Ni–20.6 Nb–40.2Ta (wt%) as reinforcements to

Light metal matrix composites with amorphous alloys/bulk metallic glass reinforcements (BMG). In: *Metallic Amorphous Alloy Reinforcements in Light Metal Matrices*. Springer, pp. 85–106.

Fig. 4 XRD spectra (a) and DSC curve (b) of the $Zr_{43}Cu_{45}Al_{12}$ bulk metallic glass particles. Reproduced from Dąbrowa, J., Perriere, L., Stygar, M., *et al.*, 2015. Oxidation behavior of $Zr_{43}Cu_{45}Al_{12}$ bulk metallic glass at 400–525°C in air atmosphere. *Journal of Materials Engineering and Performance* 24 (12), 4863–4869.

aluminum matrix resulted in 25% improvement in compressive strength of composites when compared with the unreinforced Al. Wang *et al.* (2014) fabricated the $Al_{84}Gd_6Ni_7Co_3$ metallic glass-reinforced Al matrix composite using hot pressing followed by extrusion and reported their microstructures and tensile properties. As a comparison, addition of 20 vol% of $Al_{84}Gd_6Ni_7Co_3$ reinforcement into aluminum matrix resulted in an enhancement in the yield strength and tensile strength from 75 MPa, 120 MPa for pure Al to ~93 MPa, ~157 MPa respectively. Scudino *et al.* (2009) investigated the structural and mechanical properties of Al reinforced with mechanically alloyed $Zr_{57}Ti_8Nb_{2.5}Cu_{13.9}Ni_{11.1}Al_{7.5}$ glassy particles using the powder metallurgy technique. A significant improvement in compressive strength was reported as compared to Al.

Reddy *et al.*, 2018c investigated the effect of milling time and concentration of amorphous alloy ($Cu_{50}Ti_{50}$) particles (0–15 wt%) on the microstructure and mechanical behavior of the aluminum metal matrix composites. The composites were synthesized by mechanical alloying and microwave sintering approach. The amorphous powders of $Cu_{50}Ti_{50}$ produced by ball milling were reinforced into the Al matrix. The test results have indicated that the incorporation of amorphous reinforcement into Al matrix results in improved hardness and compressive properties as compared to pure Al. Kim *et al.* (2012) used the powder metallurgy technique to fabricate brass-matrix composites by reinforcing brass matrix with $Ni_{59}Zr_{20}Ti_{16}Si_2Sn_3$ glassy particles (40 and 60 vol%). The results indicated that composites exhibited superior compressive strength as compared to brass material. Rezaei *et al.* (2016) studied microstructural and mechanical properties of aluminum-based composites reinforced with $Al_{65}Cu_{20}Ti_{15}$ metallic glass particles (0, 5, 10 and 15 vol%) through equal channel angular pressing (ECAP) method. Uniform distribution of metallic glass particles was observed with no interfacial reaction. The Al-10vol% $Al_{65}Cu_{20}Ti_{15}$ composite showed an increase of 52% in strength when compared to pure Al.

Production of Metallic Amorphous Particles/Bulk Metallic Glasses: Mechanical Alloying

Powder Metallurgy (PM) is recognized today as one of the most important manufacturing processes for producing industrial components. In particular, the growth of PM was phenomenal during the last quarter of the 20th century with the development of novel material processing techniques such as mechanical alloying (MA), atomization, rapid solidification process (RSP) etc., for powder production.

Among these, amorphous metals/metallic glasses are widely processed using mechanical alloying. Mechanical alloying is a powder metallurgy-based technique, which produces pure metallic powders through repeated cold welding, fracturing, and re-welding of the particles. Initially, raw metal powders of required composition were blended and mixed in a steel vial in a ball-mill. The mixed elemental powder particles are then subjected to extensive grinding in the vial using a grinding medium (usually stainless steel/tungsten carbide/alumina balls) and are agitated at high speeds for a desired period of time (high energy ball milling) until the required composition/structure/reaction is established. The amorphization during the mechanical alloying process occurs by solid-state interdiffusion reactions, which remove the long-range ordered crystal structure and gives rise to the amorphous structure. The basic concept of amorphization and its mechanism by high energy mechanical alloying is shown in Figs. 5 and 6 (Hellstern and Schultz, 1986; Suryanarayana, 2001).

Synthesis of Amorphous Particles Reinforced Al Composites

There are many techniques available to develop amorphous particles reinforced Al composites such as powder metallurgy, microwave sintering and infiltration casting (Lee *et al.*, 2004; Scudino *et al.*, 2009; Jayalakshmi *et al.*, 2013; Wang *et al.*, 2014; Issa *et al.*, 2017;

Fig. 5 Schematic showing the basic concept of amorphization (left), amorphization produced by the high energy ball-milling process (right). Reproduced from Suryanarayana, C., 2001. Mechanical alloying and milling. Progress in materials science 46 (1–2), pp. 1–184.

Fig. 6 Shows the schematic of the process from crystalline-to-amorphous transformation by high-energy ball-milling process. Reproduced from Suryanarayana, C., 2001. Mechanical alloying and milling. Progress in materials science 46 (1–2), pp. 1–184.

Reddy *et al.*, 2018c). Among those, the microwave sintering technique has emerged as a promising technique to develop high performance metal matrix composites (Jayalakshmi *et al.*, 2013). This technique carries salient advantages such as (1) rapid heating, (2) internal heating, (3) selected heating, (4) high heating efficiency, (5) rapid, (6) good temperature control, (7) high heating uniformity, and (8) clean energy source. A schematic diagram of the microwave sintering furnace is presented in Fig. 7.

The microwave sintering process sinters materials at higher temperatures within a relatively shorter period. Due to the shorter duration of processing time involved in this process, any undesirable reactions at the matrix/reinforcement interface are usually prevented. In contrast, in the conventional sintering methods, long duration of sintering time is necessary, which unavoidably gives rise to non-beneficial interfacial reactions.

During the synthesis process, the amorphous reinforcements are incorporated into Al- powder (matrix) at different volume fractions by the cold compaction method. Prior to cold compaction, the matrix and amorphous reinforcement are blended using the ball-milling technique to ensure uniform mixing. These powders are uniaxially compacted at a pressure of ~ 100 bar to obtain compact green billets of the desired size, which can be 36 mm in diameter and 40 mm in height. This green compact is then sintered for a pre-determined time using hybrid microwave sintering (MWS) methodology. The uniform heating of the billet using hybrid microwave helps in achieving near dense bulk nanocomposites as compared to the conventional sintering process. Moreover, the environmental friendly approach of hybrid microwave sintering helps in achieving better end-application properties with a massive reduction in processing time and costs. After this primary processing, the composites are subjected usually to the hot extrusion process at 350°C to obtain cylindrical rods of ~ 7 mm to 10 mm in diameter. The extruded rods were used for characterization and testing.

Properties of Amorphous Particles Reinforced Aluminum Metal Composites

Amorphous particles reinforced aluminum (Al) metal matrix composites have been extensively developed by many researchers because of their superior properties compared to other aluminum alloys such as low density, attractive cost, high strength with lightweight and ease of fabrication. The copper (Cu), zirconium (Zr), niobium (Nb), nickel (Ni) etc., are the most common amorphous nanoparticles used as a reinforcement to synthesize amorphous particles reinforced Al composites.

Svéda *et al.* (2013) developed $\text{Cu}_{54}\text{Hf}_{36}\text{Al}_{10}$ amorphous composite particles using ball milling.

Fig. 12 SEM micrographs of the composites with (a) 5, (b) 10, and (c) 15 vol% of AMG reinforcement particles. Reproduced from Rezaei, M.R., Razavi, S.H., Shabestari, S.G., 2016. Development of a novel Al–Cu–Ti metallic glass reinforced Al matrix composite consolidated through equal channel angular pressing (ECAP). *Journal of Alloys and Compounds* 673, 17–27.

The effect of ball milling time on the structure of the amorphous composite was analysed. Fig. 7 depicts the XRD patterns of $\text{Cu}_{54}\text{Hf}_{36}\text{Al}_{10}$ composites. The XRD patterns of these amorphous reinforced Al composites reveal the broad peak formation in the range of 32° – 45° , which confirms the formation of the amorphous phase. Furthermore, the XRD spectra of $\text{Cu}_{54}\text{Hf}_{36}\text{Al}_{10}$ shown in Fig. 8 also explains the effect of milling time on the amorphous composite. The longer milling time for 20 h results in the formation of 95% of the amorphous fraction in the structure.

Jayalakshmi *et al.* (2016) incorporated $\text{Ni}_{60}\text{Nb}_{40}$ in pure aluminum using microwave sintering technique. The structural analysis indicates that are only crystalline peaks observed in the case of Al. On the other hand, the composite structure Al-15% $\text{Ni}_{60}\text{Nb}_{40}$ shows amorphous structure like $\text{Ni}_{60}\text{Nb}_{40}$ amorphous powder with no shift. (Fig. 9).

Markó *et al.* (2014) reported the effect of different volume fractions (10, 20, 30 and 40 vol%) of $\text{Fe}_{49.9}\text{Co}_{35.1}\text{Nb}_{7.7}\text{B}_{4.5}\text{Si}_{2.8}$ amorphous particles in Al matrix using planetary milling. Fig. 10 explains the optical microscopy of the extruded amorphous composites. The presence of dark particles in the matrix confirms the incorporation of amorphous reinforcements in the composites. Furthermore, uniform distribution of amorphous reinforcements without any agglomerations explain the effectiveness of mixing these powders using planetary milling.

Jayalakshmi *et al.* (2018) studied the Al-30 wt% $\text{Ni}_{60}\text{Nb}_{40}$ developed by mechanically alloying and sintering (823K) followed by hot pressing and extrusion. The study presents the scanning electron microscopy (SEM) of the 20 h milled $\text{Ni}_{60}\text{Nb}_{40}$ and the hot extruded nanocomposites (Fig. 11). The study illustrates the addition of amorphous reinforcements (bright particles) in the dark matrix Al without any side reaction zones. The $\text{Ni}_{60}\text{Nb}_{40}$ particles are randomly distributed, and the interface between the reinforcements and matrix is quite clear.

Rezaei *et al.* (2016) developed amorphous Al matrix composites using amorphous $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ reinforcement adopting equal channel angular pressing method. The SEM images of the developed amorphous composites presented in Fig. 12 shows a well-defined morphology without any fracture.

It can be observed that the amorphous reinforcement particles are homogeneously distributed in Al-5 vol% of $\text{Al}_{65}\text{Cu}_{20}\text{Ti}_{15}$ composite without any agglomeration (Fig. 12(a)). Furthermore, it is reported that the homogeneity of decreases with its increasing volume fraction of the reinforcement. The fact of decreasing the particle homogeneity can be regarded as the effect of clustering of reinforcement with the increasing volume fraction.

Zhang *et al.* (2018) reinforced Al with CuZrAl particles using mechanical alloying and spark plasma sintering. The microscopical analysis of the developed amorphous composite presented in Fig. 13 confirms that the Cu and Zr elements exhibit a uniform dispersion state. Therefore, it indicates that CuZrAl particles uniformly distributed in the Al matrix after the appropriate mixing time.

Microstructure and property characterization of Al-based composites reinforced with CuZrAl particles fabricated by mechanical alloying and spark plasma sintering. *Advanced Powder Technology* 29 (7), 1695–1702.

Fig. 14 TEM image showing the clear interface in the composite containing Al matrix reinforced with $\text{Ni}_{70}\text{Nb}_{30}$ metallic particles. Reproduced from Yu, P., Venkataraman, S., Das, J., *et al.*, 2007. Effect of high pressure during the fabrication on the thermal and mechanical properties of amorphous $\text{Ni}_{60}\text{Nb}_{40}$ particle-reinforced Al-based metal matrix composites. *Journal of materials research* 22 (5), 1168–1173.

Fig. 15 Microhardness of the SPS-ed pure Al and Al-CuZrAl composites. Reproduced from Zhang, L., Li, B., Wu, H., *et al.*, 2018. Microstructure and property characterization of Al-based composites reinforced with CuZrAl particles fabricated by mechanical alloying and spark plasma sintering. *Advanced Powder Technology* 29 (7), 1695–1702.

Yu *et al.* (2007) synthesized Al- $\text{Ni}_{70}\text{Nb}_{30}$ amorphous composite using powder metallurgy route. The sintering temperature used in the study for the fabrication of the composites was below the melting temperature of Al (730K). The transmission electron microscopy (TEM) of the sintered sample shown in Fig. 13 explains the adequate bonding of $\text{Ni}_{70}\text{Nb}_{30}$ with the Al matrix and the formation of the pore-free surface and any reaction zones. Furthermore, selected area electron diffraction (SAED) pattern shown as an inset in Fig. 14 confirms the amorphous nature of the reinforcement.

Zhang *et al.* (2018) reinforced different vol% of the alloyed CuZrAl metallic amorphous particles into the Al matrix using spark plasma sintering technique. They evaluated the mechanical properties of the developed composites. It is reported that the microhardness of the composites increases with an increasing volume fraction of the amorphous (CuZrAl) reinforcement (Fig. 15). The maximum improvement in the microhardness was achieved at 20 vol%. Thereafter the value of microhardness showed a declining trend.

Jayalakshmi *et al.* (2013) studied the properties of Al-based composites developed by reinforcing Al matrix with amorphous $\text{Ni}_{60}\text{Nb}_{40}$ alloy powders using two directional microwave sintering technology followed by hot extrusion. It is reported that amorphous reinforcements contribute significantly to enhance the mechanical properties of the Al- $\text{Ni}_{60}\text{Nb}_{40}$ amorphous composites. The compressive yield strength of the developed composites demonstrated an increase of ~40 to 100% with the increasing vol% of the reinforcement ($\text{Ni}_{60}\text{Nb}_{40}$) when compared to pure Al (Fig. 16).

Rezaei *et al.* (2016) also reported in his findings of the compression behavior of the developed amorphous composites using various concentrations of amorphous reinforcement also called as amorphous bulk glasses (AMG). It is revealed that the strength of the developed composites exhibits a significant improvement with the increasing volume fraction of the amorphous reinforcement till 10 vol%. This improvement in strength is considered to be the effect of dispersion hardening effect of the hard

reinforcement particles. Furthermore, it is also noticed that there is a decrease in the strength with further increase in the amount of reinforcement (Fig. 17).

The composite containing 15 vol% reinforcement (Al-15 vol%) shows a decrease in strength which can be associated to the agglomeration of the amorphous reinforcement. Clustering of the particles enhance the local stress concentration and hence provide the site for crack propagation in these amorphous reinforced composites. The crack propagation leads to work softening behavior.

Zhang *et al.* (2018) studied the tensile behavior of the developed $\text{Al}_{84}\text{Gd}_6\text{Ni}_7\text{Co}_3$ reinforced Al composites prepared by powder metallurgy route followed by hot pressing and extrusion. The tensile properties (Fig. 18) reveal a significant increase in the yield and ultimate strength of the developed composites compare with the pure Al. In addition, the ductility of the sample is reported to be reduced by 13%. The increase in the strength and decrease in the ductility is ascribed to the hard and brittle nature of the amorphous reinforcement.

Many studies have also conducted to understand the failure mechanism of amorphous particles reinforced Al-based composites. Fig. 19 shows the SEM images of the failed tensile samples having a different volume fraction of $\text{Ni}_{60}\text{Nb}_{40}$. A ductile fracture is reported in the tensile failure of the samples. It is observed that the amorphous reinforcement has a fine interfacial connection with the matrix without any noticeable debonding. The ductile fracture of the matrix without any cracks confirms the efficient load transfer of the amorphous reinforcement. Moreover, the cracking of amorphous particles (arrows in Fig. 19) is also noticed, which can be due to the localized stress distribution.

In order to expand the area of utilization of amorphous particle reinforced composites, it is essential to evaluate their anticorrosion properties. Some reports are available in the literature addressing the corrosion resistance these composites. For example, the corrosion resistance of Al reinforced with CuZrAl is included here. The potentiodynamic polarization curves of the pure Al and the developed Al-CuZrAl amorphous composites are presented in Fig. 20. A comparison of anodic and cathodic curves shows that the corrosion resistance increases with the incorporation of CuZrAl reinforcement, suggesting an effective role of CuZrAl as an affective reinforcement to develop passive layer in the harsh corrosive environment. This is important when considering the application of these materials in an aggressive environment. Al-based composites are likely to be attacked by Cl⁻, which facilitates the formation of a passive layer of Al₂O₃ over the surface, which protect the composites from the adverse effect of corrosive species. Moreover, the presence of Zr in the composite leads to form Al₃Zr, which also enhances the anodic protection of the developed composites.

Conclusions

The current article has explained in detail the introduction, synthesis techniques and properties of the amorphous reinforced Al base composites. Based on the reported research work, the following conclusions are made;

- Amorphous reinforced Al metal matrix composites possess a unique structure capable of demonstrating superior mechanical and anti-corrosive properties.
- Although amorphous reinforced Al metal matrix composites can be developed by many techniques, however, microwave sintering technique is more appealing due to its salient advantages over the conventional sintering approach.
- Amorphous reinforced Al metal matrix composites demonstrate decent mechanical properties well suited to many industrial applications.
- Finally, the promising anticorrosive properties of amorphous reinforced Al matrix composites extend their utilization to the marine application as well in addition to aerospace, automobile etc.

Introduction

The continuous depletion of fossil fuels and serious environmental problems caused by the ever-increasing global economy have triggered severe threats to the survival and development of humankind. Consequently, exploring novel materials with multifunctionality is fundamental for the sustainable development of the economy and society (Wu *et al.*, 2019). The traditional approach to the development of materials and structures addresses the load carrying function and other functional requirements separately, resulting in a suboptimal load-bearing structure with add-on attachments that perform the non-structural functions with the penalty of added weight. Recently, however, there has been an increased interest in the development of multifunctional materials that are designed to perform (1) multiple structural functions simultaneously, (2) combined non-structural and structural functions, or (3) both.

In this regard, lightweight high-performance composites gain attention due to their higher specific properties, ease of fabrication, and tailorability in properties (Gupta and Wong, 2015; Thornby *et al.*, 2019, 2021; Parande *et al.*, 2020). One of the easiest ways of decreasing the weight of the structures is to remove material from them. This can be done by imparting air packets inside the materials in the form of porosity. In this context, these materials can be classified as open cell and closed cell foam composites (Patil *et al.*, 2019a,b; Singh *et al.*, 2019; Doddamani, 2020). The open cell foams consist of channels or pockets of air throughout the material's microstructure (Montminy *et al.*, 2004; Jang *et al.*, 2008). Although open cell foam method reduces weight, it can potentially undermine the structure's structural integrity as there is a lack of controllability of the pores (Bharath *et al.*, 2020, 2021a,b; Bonthu *et al.*, 2020; Gupta and Doddamani, 2020; Sailesh *et al.*, 2021).

One of the novel ways of imparting porosity in structures is to enclose the porosity inside stiff shells. These materials are called syntactic foams, wherein hollow microballoons are enclosed inside a matrix material (Doddamani *et al.*, 2011; Manakari *et al.*, 2015; Waddar *et al.*, 2018, 2019). Incorporating porosity through hollow particles instead of embedding air/gas voids provides a reinforcing effect to each pore and imparts properties similar or superior to what would be found in monolithic cellular materials, in particular metallic foams (Omar *et al.*, 2015). The incorporation of porosity in material makes the material lightweight and enhances compressibility. Energy absorption and ductility can be further enhanced by increasing the extent of porosity (Ashrith *et al.*, 2019; Manakari *et al.*, 2019; Shahapurkar *et al.*, 2019). Open cell foams lack strength and modulus limiting their application. Metal matrix syntactic foams (MMSFs) exhibit superior mechanical properties due to closed cell structure for the same amount of porosity (Rohatgi *et al.*, 2011). The plateau strength and densification strain are also closely related to porosity in the foam composite. Lightweight foam composites with high energy absorption capacity can be used to reduce shock loadings against impact, for example, in mining and automotive industries (Tao *et al.*, 2009).

An illustration of a syntactic foam microstructure is presented in Fig. 1. Several phases exist in the microstructure, as shown in the Fig. 1. The varying parameters in synthesizing syntactic foams include choosing the matrix and microballoon materials, the volume fraction, and the density of the microballoons. The density of the microballoons is determined by the wall thickness parameter of the reinforcing microballoon. The microballoon wall thickness is characterized by radius ratio (η) as

$$\eta = R_i/R_o$$

where R_i and R_o are the inner and outer radii of the microballoon. Fig. 2 shows the illustration of the variation in the wall thickness parameter of the microballoon. So, by controlling the volume fraction and wall thickness parameter of the microballoon, the effective mechanical, thermal, biological properties of the composites can be tailored. This tailorability capability of the syntactic foams makes it an ideal candidate to be used in weight saving applications (Fig. 3).

Hollow Particles

Fly Ash Cenospheres

The presence of hollow particles has traditionally exhibited isotropic properties, better compressive strength and modulus, high strength to weight ratio, and good energy absorption (Rohatgi *et al.*, 2011). However, cost remains a significant barrier in the widespread use of metal matrix composite components in the industry. The utilization of fly ash particles, a by-product of the coal-fired power plants, as reinforcement can drastically reduce the cost of the metal matrix composites. Moreover, the application of fly ash cenosphere particles in the syntactic foam system effectively utilizes industrial waste, thereby reducing carbon dioxide emissions. Fly ash cenospheres are generally gray to buff in color, between 0.5 and 100 μm in diameter, with silica and alumina being the major constituents. The fly ash particles are like hollow micro balloons with a true density of 0.4–1 g/cc and are spherical where the sphericity is very close to 100%. An example of cenospheres is presented in Fig. 4(a). The low density encourages its usage in developing lightweight composites (Rohatgi *et al.*, 2006). Composite foams have been prepared in the past with fly ash

particles into the metallic and polymeric matrices (Gupta *et al.*, 2013; Gupta and Rohatgi, 2014). Some of the cenospheres may have porosity embedded in their shell, as seen in Fig. 4(b) (Gupta *et al.*, 2012).

Many researchers have studied the effect of fly ash particles in aluminum and magnesium matrix composites. Owing to their energy-intensive production methods, the replacement of part of Al and Mg by fly ash particles promises considerable energy savings (Rohatgi *et al.*, 1996). Metal matrix syntactic foams (MMSFs) with hollow particle volume fractions as high as 60% have been synthesized (Gupta *et al.*, 2012). At such a high-volume fraction, the syntactic foams exhibit a density in the range 1–1.5 g/cc, which is directly comparable with the polymer matrix composites. The higher melting points, ductility, and modulus of the MMSFs make them more desirable when compared to

Fig. 4 (a) Fly ash cenospheres; (b) Defects present in some cenospheres may include irregular shape, nonuniform wall thickness, and porous walls. Reproduced from Gupta, N., *et al.*, 2012. Magnesium matrix composite foams—density, mechanical properties, and applications. *Metals* 2 (3), 238–252.

polymer matrix composites (Gupta *et al.*, 2012). Over the years, the concept of syntactic foams is very well established for aluminum and polymer systems (Mukai *et al.*, 1999; Kanahashi *et al.*, 2001; Wen *et al.*, 2004; Solórzano *et al.*, 2008). The aluminum matrix fly ash composites have been used to fabricate various components like pistons, connecting rods, and engine covers (Rohatgi *et al.*, 1996; Matli *et al.*, 2020a). The research on magnesium matrix syntactic foams is increasing as the density of magnesium is $\sim 35\%$ lower than aluminum (Hartmann *et al.*, 1998; Manakari *et al.*, 2016, 2017, 2020; Matli *et al.*, 2020b; Prasad *et al.*, 2020; Padnuru Sripathy *et al.*, 2021).

Although cenospheres possess numerous advantages, the lack of ability to control their production tends to result in inherent randomness in cenosphere quality. Examples of potential defects include variability in wall thickness as well as the presence of particle porosity. The former can result in “premature” failure of the hollow particle, either in processing or in the initial stages of loading. The presence of surface porosity can result in the filling of hollow particles during processing, thereby eliminating the contribution of the hollow particle to a lower overall foam density as well as an increase in energy absorbing capability.

Engineered Hollow Particles

Besides the massive popularity of lightweight composites, the interest in hollow particles is also ever increasing for several applications, and several techniques are now available to synthesize such particles of controlled composition and quality (Károly and Szépvölgyi, 2003; Hyodo *et al.*, 2005; Watanabe *et al.*, 2007). The engineered hollow particles produced from these methods are typically called microballoons. Microballoon is often used to reference hollow particles that are not created as a by-product of the combustion process, i.e., cenospheres. A variety of techniques are used to produce microballoons with controlled sizes and properties. For example, in the late 1980s, a method for producing microballoons was developed that started introducing polystyrene balls into an air current above a fluidized bed. The balls were then coated with a suspension of metal or ceramic powder and binder. After the desired coating thickness was reached, the balls were subjected to heat treatment which burned off the polystyrene and other organic components. The resulting particles were then sintered just below the melting temperature to form a hard and cohesive shell. This approach is currently used by Hollomet GmbH (Dresden, Germany) to make both particles and foams in a variety of materials. Further details of this method may be found in Öechsner and Augustin (2009).

Similarly, Deep Spring Technology (Toledo, OH) has developed the capability of producing a broad variety of ceramic and metal hollow particles suitable for metal matrix syntactic composites. They have matured the manufacturing process such that hermetic (gas tight) ceramic hollow particles made of silicon carbide, boron carbide, and alumina oxide are produced, which now are commercially available. The increased size range and uniformity of the current hollow particles may be useful in developing lightweight composites with a higher level of strength and modulus than glass or fly ash hollow particles. Hollow spheres of diameters ranging from less than 1 mm to more than 10 mm are commercially available, as shown in Fig. 5. Fig. 5 also shows a uniform wall thickness in hollow particles, with a wall thickness to outer diameter ratio of about 32:1.

In addition to methods described above, several novel techniques have been developed to produce a variety of ceramic, carbon and glass hollow particles such as powder slurry method, ion extraction of colloidal alumina sols, ceramic slurry technique, microfluidic process and solid templating technique which aim at improving the cost, quality and reproducibility of the hollow fillers. Usually, engineered hollow particles have controlled structure and properties and offer better properties compared to fly ash cenospheres. In addition, their surfaces can be engineered to increase compatibility with the matrix metal or alloy.

Processing Techniques

The mechanical properties of the MMSFs mainly depend on the uniform dispersion of reinforcements within the metal matrix. The higher the hollow particle distribution, the more is the synthesis technique considered efficient. The methods to obtain syntactic foams are stir casting, pressure infiltration, powder metallurgy, and disintegrated melt deposition (Fig. 6).

Fig. 5 (a) Alumina hollow particle; and (b) the surface of the alumina particle (Courtesy Deep Springs Technologies, Toledo, OH, USA).

Stir Casting

In the stir casting technique, the stirring of molten metal is realized by using a high shear impeller with particles into the vortex formed in the melt. The molten metal is immediately poured into a sand mold and further allowed to cool and solidify. Stir casting is a low cost process and requires basic foundry infrastructure (Daoud *et al.*, 2007). However, the flotation of low-density hollow particles is a major drawback in this process primarily when the particle volume fraction is low. Wetting of particles with liquid melts and chances of particle fracture for high volume fraction are also significant disadvantages of this process (Rohatgi *et al.*, 2011). Some researchers have also suggested using coatings to seal the porosity of the hollow fly ash micro balloons (Rajan *et al.*, 2007; Surappa, 2008).

Pressure Infiltration

In the pressure infiltration technique, a preform of loosely packed particles is placed in mould (Liu *et al.*, 2012). The molten metal matrix is infiltrated into the mold with the application of either high pressure or vacuum or both to form a near-net-shaped syntactic foam component by filling the inter-particulate spacing (Zhang and Zhao, 2007). Infiltration of loose beds of cenospheres with molten alloys to form syntactic foams can eliminate the need for preform preparation. To avoid incomplete infiltration and the freeze choking of the melt, establishing control over particle preheat temperature and melt superheat temperature is critical (Rohatgi *et al.*, 2011). The major advantages of this process are (1) synthesis of syntactic foams with higher particle volume fraction of up to 70% with low porosity and (2) near-net-shaped components. The limitations of this technique are that high infiltration pressure can cause fracture of hollow particles and infiltration of liquid metal into the hollow spaces of the cenospheres. On the other hand, low infiltration pressure may result in high residual porosity due to incomplete filling of pores (Rohatgi *et al.*, 2011).

Powder Metallurgy

Powder metallurgy is a type of solid-phase processing method. This technique is very flexible as it can synthesize composites with a wide spectrum of particle volume fractions. The hollow particles are thoroughly mixed with the metal matrix material and further compacted under pressure. The resulting component is known as a “green compact”. This green compact is sintered using either conventional or microwave assisted sintering techniques to obtain a syntactic foam (Hrairi *et al.*, 2009; Gupta and Wong, 2015). The powder metallurgy technique can synthesize reactive materials, which are not controllable in liquid-phase processing. During the synthesis of high particle volume fraction composites, the fracture of weak hollow particles was observed during the compaction stage. Hence, this method is best suited to synthesize low fly ash volume fraction syntactic foams (Rohatgi *et al.*, 2011).

Disintegrated Melt Deposition (DMD)

DMD is a unique cost-effective technique that brings together the advantages of conventional casting and spray processing, utilizing lower impinging gas jet velocities and higher superheat temperatures to produce bulk composite material (Fig. 7). Synthesis of hollow particle reinforced magnesium composites using DMD technique involves heating the reinforcement powder and magnesium chips/turnings in a multi-layered ordering to a superheat temperature (750°C) in a graphite crucible with a resistance heating furnace under the influence of an inert argon gas atmosphere. The crucible is equipped with an arrangement for bottom pouring. Upon reaching the superheat temperature, the molten slurry is stirred using a Zirtex coated steel impeller for 5 min at approximately 450 rpm for uniform distribution of hollow particles in the metallic matrix. The stirring also ensures homogeneity in crucible temperature. The composite melt is disintegrated by two jets of argon gas orientated normal to the melt stream before being deposited onto a metallic substrate to obtain a preform. Fine equiaxed grains, uniform distribution of reinforcements, and faster solidification of atomized melt leading to decreased porosity and improved properties are some advantages of the DMD technique. The material wastage is also very minimal in

Fig. 6 Most common production methods of MMSFs.

the DMD technique. The main limitation of this technique is the difficulty of incorporating reinforcements with high volume fraction due to increased viscosity. This increase in viscosity leads to the heterogeneous distribution of reinforcements and difficulty in stirring. However, this limitation is not critical as the optimal volume fraction above which further addition of reinforcements won't affect the properties of the composites is already below the limits of this technique (Gupta and Wong, 2015).

Secondary Processing Techniques

Secondary processing like rolling, forging, and extrusion is used to further improve the properties of composite materials. However, in the case of syntactic foams, the mechanical and physical properties mainly depend on the matrix porosity and the native integrity of hollow particles. The strength and modulus of syntactic foams can be altered by varying the matrix microstructure. Due to the presence of a large amount of porosity, secondary processing of syntactic foams is not recommended. The properties of syntactic foams can be further enhanced by heat treatment (Gupta and Rohatgi, 2014).

Microstructure of MMSFs

Microstructure of the syntactic foams is found to vary based on the combination of matrix and alloy as well as on the potential application. Uniform distribution of particles in the matrix is the primary factor important for such MMSFs. A number of other microstructural concerns exist in studying syntactic foams, as discussed below.

A representative microstructure of Mg/cenosphere and AZ91D/cenosphere syntactic foams are shown in Fig. 8(a) and (b) respectively. The results of microstructural characterization in various studies (Daoud *et al.*, 2007; Rohatgi *et al.*, 2009; Huang *et al.*, 2010; Liu *et al.*, 2012) have reported the morphology and distribution of hollow particles and secondary phase particles of the composite foams as well as presence of some micro-voids at the particles/matrix interface. It has been observed that the amount of hollow particles is always less represented in the microstructure than the actual target value. This results from the replacement of hollow particles by the metal matrix due to pre-existing defects and cracks. Further, there will be intermetallic particles forming due to the reaction between the elements in the particle walls and matrix. Depending on the formation and distribution in the composites, the intermetallic particle layer formation can affect the mechanical properties of the syntactic foams. For example, in fly ash cenospheres reinforced ZC63 (Daoud *et al.*, 2007) and AZ91D (Rohatgi *et al.*, 2009; Huang *et al.*, 2010; Huang and Yu, 2011) alloys, MgAl_2O_4 , MgO and Mg_2Si are formed at the interface of the cenosphere and the matrix. In contrast, spheroidal Mg_2Si and $\text{Mg}_{17}\text{Al}_{12}$ are known to form in the matrix. Also, MgAl_2O_3 which may be generated,

further reacts with Mg and decomposes into MgO and Al (Gupta *et al.*, 2012). Fig. 9 shows the AZ91D microstructure with typical precipitates. Reaction products may be generated due to the interfacial reactions and may diffuse in the matrix in the inter-particle region. Some of the reaction products may accumulate at grain boundaries, which is undesirable. Al–Si alloy filled with hollow glass particle is found to have reactions with the SiO_2 present in the particles to produce MgAl_2O_4 .

Mechanical Properties

Compressive Properties

Due to their low density, high hydrostatic compressive strength, high damage tolerance, low moisture absorption coefficient, and good electromagnetic interference (EMI) shielding, and polymer syntactic foams have found wide applications as buoyancy modules for marine applications and underwater explorer vehicles (Gupta *et al.*, 2018). In such applications, these syntactic foams are often subjected to severe compressive loading, which can indicate areas where MMSFs can be useful. The properties of MMSFs can be tailored by a number of parameters such as type of the particle shell, shell wall thickness to diameter ratio, a combination of matrix alloy and particles, processing parameters, volume fraction, porosity, and heat treatment (Gupta *et al.*, 2012). All these parameters are found to

Fig. 9 AZ91 matrix microstructure showing precipitates. Reproduced from Gupta, N., *et al.*, 2012. Magnesium matrix composite foams—density, mechanical properties, and applications. *Metals* 2 (3), 238–252.

influence the mechanical properties as well as the density of the composite. The presence of controlled size porosity of a spherical shape with uniform distribution aids in providing high energy absorption under compression in syntactic foams (Rohatgi *et al.*, 2011). Therefore, syntactic foams are primarily designed to be used under compression. Incorporating stiff ceramic particles like cenospheres or glass microspheres in the syntactic foam structures helps obtain high modulus and strength as the particles act as load-bearing elements under compression (Gupta and Woldesenbet, 2004). As a result, most of the publications in the open literature have studied the compressive properties of MMSFs for a large number of metal matrices, including aluminum, magnesium, titanium, iron, Invar, zinc, and lead matrix syntactic foams reinforced with fly-ash cenospheres, glass microspheres and other engineered hollow particles such as alumina, silicon carbide, and boron carbide. Most of the mechanical data available for MMSFs are measured under quasi-static conditions, while the response of these foams to dynamic, tensile, and cyclic loading is limited to a subset of the materials available and provides the first indication of capabilities rather than comprehensive accounts of their performance. This section provides an overview and general references and trends regarding the most important properties of the MMSFs and comparison charts for material selection.

The red line illustrates a typical compressive stress-strain graph of a typical syntactic foam specimen in Fig. 10. The deformation characteristics of syntactic foams under compression are similar to those of conventional metal foams, and their stress-strain curves exhibit four distinct points, as shown in Fig. 10. For MMSFs, compressive strength and plateau stress are two properties that require attention. The compressive strength is defined as the peak stress after the linear elastic region in the stress-strain curve. At this peak, the failure of the hollow particle starts. The initial failure of hollow particles can be due to defects, such as cracks present in the hollow sphere walls. These relatively thin walled hollow spheres may have lower strength than other hollow spheres or localized stress concentrations resulting from factors like a group of closely spaced figures. Following the linear region appears the plateau region where the stress rises smoothly with increasing strain in the collapse region, indicating no strain hardening in the syntactic foam specimen during plastic deformation. The onset of the plateau region is governed by the fracture strength of the hollow particle shells and is realized once the stress is low enough for the bulk material to sustain a homogeneous compression. Depending on the particle wall thickness and volume fraction, the stress plateau can extend to over 50% densification strain depending on the total porosity in MMSFs. The compressive strength and plateau stress are important properties because the compressive strength is considered the maximum stress before the hollow particle fails, and the plateau stress related to the energy absorption capabilities of the MMSFs. In general, these values increase with the volume fraction of hollow particles.

Several possibilities exist for the superior compressive properties observed for syntactic foams when compared to conventional metal foams. Usually, pore collapse occurs at low applied compressive stresses in traditional foam of metal, whereas in syntactic foams, the pores are surrounded by stiff, strong ceramic walls, which impede their deformation and collapse during compressive loading, increasing the MMSF stiffness and strength (Fig. 11). The yielding behavior of MMSFs is influenced by a complex concurrence of processes such as the extent of hollow particle breakage, plastic deformation behavior of the matrix, and characteristics of the interface, including interfacial reaction and resultant interfacial bond strength, dislocations and load sharing between the reinforcement and the matrix. At lower volume fractions, the yield strength of the MMSFs is dominated by the strength of the reinforcing phase, whereas with increased filler loadings, both the matrix and the hollow particles contribute to strength. At higher volume fractions, the hollow particles contribute to the stress accommodation due to an increase in the matrix-particle interface resulting in higher yield strengths for MMSFs. Further, the possibility of controlling the uniform pore size and volume fraction of the porosity that can be reinforced into the metal matrix provides an opportunity to tailor the compressive properties of MMSFs to meet specific application requirements.

However, it should be noted that not all the MMSFs reported in the literature exhibit this true syntactic foam behavior, i.e., a horizontal, constant-stress plateau region extending over a significant strain range. Compression curves for several magnesium and iron syntactic foams reinforced with fly-ash cenospheres, glass microspheres and metal hollow spheres show a positive inclination at strains between initial yield and densification resulting from high work hardening of the matrix and fracture of particle causing compaction. The high reactivity of magnesium and processing challenges in synthesis of magnesium syntactic foams can often result in breakage of the hollow particles and infiltration of magnesium into the pore cavities resulting in compression behavior typically observed for MMCs reinforced with solid particulate fillers. Also, it has been reported that a critical threshold of 30 vol% porosity is required for MMSFs to

Fig. 10 Schematic representation of compressive stress-strain diagram of a typical MMSF specimen. The annotations in the graph refer to 1: yield strength, 2: compressive strength (peak strength), 3: plateau stress and 4: densification strain.

Fig. 11 Optical micrograph of longitudinal section of ZnAl22-25 vol% cenosphere syntactic foam after compression showing cenosphere fragments. Reproduced from Daoud, A., 2014. Zinc Matrix Syntactic and Composite Foams. Metal Matrix Syntactic Foams: Processing, Microstructure, Properties and Applications 137.

exhibit true syntactic foam behavior. Additionally, reinforcing hollow metal spheres to introduce porosity into a metallic matrix can result in similar overall behavior of the material as both the reinforcement and matrix are identical in composition, state, and relatively highly ductility. Further, the resulting compressive behavior is significantly affected by the interplay of the matrix and the hollow reinforcement. The complexity of this interplay has been illustrated by Lehmus *et al.* in a comparison study between identical volume percentages of cenospheres and S60HS glass microspheres reinforced into Fe99.7 matrix. It was observed that while the glass microspheres were found to cancel out ductility completely, cenosphere addition allowed the retention of some plasticity. Therefore, the development of special alloys to serve as matrix materials in syntactic foams should be critically looked at to obtain the best advantage of syntactic foams rather than incorporating microballoons in conventional monolithic alloy matrices. These alloys should be specially tailored to bond the microballoons by having favorable thermodynamics and kinetic for desired interfacial reactions.

Dynamic Compressive Properties

Many studies have investigated the dynamic compressive properties of MMSFs. Zhang and Zhao (2007) used the drop hammer test to study the low speed (4 m/s) impact response of Al matrix syntactic foams. Compared with static compression, the stress-strain curve of dynamic compression is different. It has oscillations at low strains because the impacting hammer experiences strong vertical vibrations when it hits the syntactic foam sample. Meanwhile, the impact peak strength is much higher than the compressive strength in static compression. (Altenaiji *et al.*, 2014) studied the characteristics of Al syntactic foams under drop weight impact and reported that impact peak strength is proportional to impact energy. Balch *et al.* (2005), Dou *et al.* (2007), Zhang *et al.* (2016, 2018) studied the impact response of Al matrix syntactic foams using Split-Hopkinson bars with high strain rates. The dynamic stress-strain curve is similar to static compression, but the compressive strength is much higher and strain rate dependent. Some of the results obtained from the literature for open- and closed-cell aluminum foams are compared with those for aluminum matrix syntactic foams in Fig. 12, where Fig. 12(a) is plotted with strain rate using normal axis and Fig. 12(b) is plotted with strain rate using log axis (Dou *et al.*, 2007; Luong *et al.*, 2011; Goel *et al.*, 2012, 2014; Rabiei and Garcia-Avila 2013; Zou *et al.*, 2013; Alvandi-Tabrizi and Rabiei 2014; Cox *et al.*, 2014; Santa Maria *et al.*, 2014).

These two modes allow more clear insight into high and low strain rate regions, respectively. The main observations from Fig. 12 are:

- Fig. 12(a) shows that most syntactic foam compositions are listed with over 100 MPa strength values, whereas foams containing gas porosity have strength values below 50 MPa for most compositions. This high strength is suited for load bearing applications. Syntactic foams have higher strength than open- and closed-cell foams at the same level of density. This observation is essential for structural applications.
- The strain rate sensitivity in aluminum-based foams is not very strong. It is known that face centred cubic metals are not strongly strain rate sensitive. Similar observations for magnesium and iron matrix syntactic foams may provide different results because of the inherent strain rate sensitivity of the matrix alloy.

The strain rate sensitivity is not limited only to mechanical properties. The failure mechanism of syntactic foams can also be strain rate dependent. As the strain rate is increased, the foam behavior transits from ductile to brittle. At sufficiently high strain rates, some of the foams fracture a minimal compressive strain. The characteristics of this type of failure include relatively less particle crushing, cracks in the specimen in the direction of compression, and suppression of shear effects.

Energy Absorption

Metal matrix syntactic foams have advantages in energy absorption because of the relatively higher plateau stress and extensive plateau regime. The former is mainly dependent upon the strengths of the metal matrix and microspheres and the volume ratio between the two. The latter relates to the densification strain, which is determined by the porosity of the syntactic foam. The specific energy absorption of CP Al matrix and Al 7075 matrix syntactic foams were about 39 and 49 J/g, respectively, which are significantly higher than those observed for unreinforced aluminum foams of similar density are comparable to steel foams fabricated by powder metallurgy (Balch *et al.*, 2005).

Weight Saving Potential of MMSFs

The weight saving potential of syntactic foams can be realized by understanding the relationship between syntactic foam density and mechanical properties. The compressive yield strength of ceramic reinforced syntactic foams normalized with the yield strength of the matrix material has been plotted for composite density in Fig. 13 to visualize the weight saving advantage. The data in the Fig. 13 represent Al, Mg, Ti, and Fe matrix syntactic foams and are taken from the available literature (Rohatgi *et al.*, 2006; Daoud *et al.*, 2007; Surappa, 2008; Daoud, 2009; Mondal *et al.*, 2009; Rohatgi *et al.*, 2009; Huang *et al.*, 2010; Xue *et al.*, 2010; Luong *et al.*, 2011; Peroni *et al.*, 2012; Luong *et al.*, 2013; Rocha Rivero *et al.*, 2013).

Some of the compressive properties presented here are extracted from the published graphs to the best possible accuracy. Also, the yield strength of the alloys that are needed to plot the Fig. 13 is taken from standard databases when it is not given in the same publication. It can be observed from Fig. 13 that the syntactic foam properties can be tailored over a wide range of strength values. The strength of several lightweight syntactic foams is equal to or close to the strength of the matrix material. Also, it can be noticed that the magnesium matrix syntactic foams have higher values of yield strength and maintain their superiority over most other types of syntactic foams. The aluminum matrix syntactic foams have yield strength values from about 30%–70% lower than that of magnesium matrix syntactic foams at comparable density. In contrast, iron syntactic foams have similar strength, their density is 2–3 times higher than the magnesium matrix syntactic foams. Weight saving can be achieved in load-bearing applications by replacing the aluminum and titanium matrix syntactic foams with magnesium matrix syntactic foams without compromising the strength. In general, higher density foams tend to have higher strength. Depending on the end requirements of the applications, appropriate material can be selected.

The novel behavior offered by MMSFs is higher specific properties. Further, the use of hollow particles such as fly ash reduces landfill sizes and minimizes environmental pollution. Further ease of processing makes them candidate materials for existing body frames of vehicles in the transportation sector, wherein energy absorption is of paramount importance. High energy absorption of the syntactic foams finds potential usage by foam-filling of the hollow parts of automobiles such as bumper systems and fenders, which may reduce injuries and damage due to impact loads (Fuganti *et al.*, 2000; Kovacik and Simancik, 2004). Further, these have been extensively used in defense applications like soldier helmets resulting in superior ballistic protection and impact resistance. Titanium and magnesium syntactic foams can be readily used as orthopedic implants in the biomedical regime, which acts as a load bearing element (Niemeyer, 1999). However, the potential of MMSFs in several other areas of applications is still not well explored.

MMSFs can be used in multifunctional applications, mainly in automotive, to serve as lightweight panels, absorb energy in crash situations and reduce acoustic emissions. They can also be used to build column structures due to their robustness and damage tolerance, making the failure less catastrophic. MMSFs can go a long way in the passive safety of the vehicles as they exhibit a reasonably long plateau range which helps in increased energy absorption. The automotive and indoor noise control is also a potential area where the feasibility of MMSFs can be explored. MMSFs can also be used for indoor sound absorption in places like auditoriums and cinemas. MMSFs with higher buckling and crippling resistance can be used to replace honeycomb structures in the aerospace turbines and also be used to replace existing load bearing structures in satellites and space vehicle landing pads (Banhart, 2001). If the central interest of material substitution is weight-saving, then perhaps there are several other cheaper materials that can be substituted other than MMSFs. However, good thermal properties, high specific strength, and energy absorption characteristics coupled with lightweight significantly increase the competitiveness of the MMSFs.

Fig. 12 Comparison of strength values for open and closed-cell aluminum foams containing gas porosity with those of aluminum matrix syntactic foams. The strain rate values are plotted on (a) normal axis and (b) log axis. In both cases the strength values are plotted on log axis. Reproduced from Gupta, N., Rohatgi, P.K., 2018. 4.15 Metal matrix syntactic foams.

Summary

In summary, this article presented the synthesis methods and mechanical properties of metal matrix composite syntactic foams (MMSFs). As the MMSFs are reinforced by hollow particles, they can also be considered as metal matrix composites. First, the constituents have been considered: the most commonly used matrices are Al alloys. Besides Mg, Zn, and Fe matrices are used, and work on Ti and Cu matrices can also be found in the literature. Subsequently, the filler materials have been summarized, emphasizing their properties, advantages, and disadvantages. Following that, the synthesis methods of the MMSFs have been grouped and discussed, emphasizing the potential of pressure die casting as a possible mass production method for MMSFs. In the

Fig. 13 Compressive yield strength of syntactic foams (σ_{ys}) normalized with the yield strength of the matrix material (σ_{ym}) plotted against density.

section about the microstructure of MMSFs, the primary imaging methods and basic inner structures have been described. Last but not least, a general insight into the mechanical properties of MMSFs has been given, discussing, in short, the quasi-static and dynamic properties of MMSFs, as well as their potential weight saving features and application areas, are highlighted.

Insight Into Layered Metal Matrix Composites

Akshay Padnuru Sripathy and Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introduction

Laminated metal composites (LMCs) are the materials formed by bonding stacked layers of two or more materials. LMCs are one of the oldest known technologies to mankind. The Japanese and Damascus swords, Indonesian Kris (Lesuer *et al.*, 1996; Forster *et al.*, 1993) etc., are few examples from the past which are made out of laminated metal composites. LMCs have gained greater research interest due to their superior mechanical strength, ductility, and corrosion resistance (Chen *et al.*, 2020; Ellis and Lewandowski, 1994). LMCs typically have one soft/ductile material coupled with hard/brittle material stacked one above the other to realize desired strength, ductility and toughness. LMCs can be broadly classified into five sub categories based on the type of materials used as: (1) metal – metal laminates, (2) metal-intermetallic laminates (MIL), (3) metal – ceramic laminates, (4) fiber-metal laminates and (5) metal-metal matrix composite laminates. Fig. 1 shows classification of LMCs. The LMCs are also called metal based laminated materials. Further sections of the article focus mostly on metal-metal matrix composite laminates.

LMCs are also classified based on the stacking sequence, as angle and cross-ply laminates which can be of symmetric, antisymmetric or balanced (Kaw, 2006). Based on number of layers, LMCs are also identified as bi-layer, tri-layered and multi-layered materials.

Metal – Metal Matrix Composite Laminates

Metal-Metal Matrix Composite laminates are a type of laminated metal composites with at least one of the material layers as metal matrix composite. Generally, MMCs used in Metal – MMC Laminate are brittle in nature and pose high strength with lack of ductility. On the other hand, the metal layer used can be pure metal or an alloy with higher ductility and toughness. Metal – MMC laminates are also called by various names which include Layered Metal Matrix Composites (LMMCs), Laminated metal matrix composites (LMMCs) and Metal Matrix Composite Sandwich Panel (Ko and Jackson, 1993).

The Metal – MMC laminates or Layered Metal Matrix Composites (LMMCs) can be further classified as Similar Metal – Metal Matrix Composite Laminates and Dissimilar Metal – Metal Matrix Composite Laminates. Similar Metal-MMC laminates are those, where monolithic MMCs are coupled with monolithic metals or alloys which are similar to the matrix of MMCs. For instance, Ti – (TiB + La₂O₃)/Ti (Duan *et al.*, 2016), Ti – TiB_w/Ti (Liu *et al.*, 2014a), Al6063 – (TiB₂ + TiC)_p/Al6063 (Chen *et al.*, 2020), AA1050 – SiC_p/AA6061 (Hosseini Monazzah *et al.*, 2014) are few titanium and aluminum based similar Metal-MMCs laminates. Dissimilar Metal – MMC laminates are those where monolithic MMCs are coupled with monolithic metal or alloys which is different from the matrix of MMCs. Ti – SiC_p/Al (Fan *et al.*, 2017), Al5083 – TiC/Cu (Tomida *et al.*, 2001), Mg – SiC/Al (Syn *et al.*, 1996) are few examples of dissimilar metal-MMC laminates.

Microscopically, MMCs consist of metal matrix with dispersed particle or fiber reinforcements. In general, introducing precipitates, particle or fiber reinforcements in metal matrix increases strength of the metal with the expense of ductility and plasticity. Similarly, MMCs often show characteristics of high strength and stiffness with low ductility (Duan *et al.*, 2016; Gao *et al.*, 2020;

Fig. 1 Classifications of laminated metal composites.

Table 1 List of properties of MMCs and LMMCs

	Material	TYS (MPa)	UTS (MPa)	Elongation (%)	
MMC	5 vol% (TiB ₂ + TiC)p/Al	111.2	152.1	10.5	Chen <i>et al.</i> (2020)
	5 vol% TiB _w /Ti	656 ± 6	720 ± 7	7.5 ± 0.2	Liu <i>et al.</i> (2014a)
	10 vol% SiCp/Al	–	156 ± 11	11.8 ± 1.2	Fan <i>et al.</i> (2017)
	5 vol% TiB _w /Ti	656	720	7.5	Liu <i>et al.</i> (2013)
	8 vol% TiB _w /Ti	672 ± 6	832 ± 7	5.9 ± 0.2	Liu <i>et al.</i> (2014b)
LMMC	Al6063–5 vol% (TiB ₂ + TiC)p/Al	247.4	255.8	11.6	Chen <i>et al.</i> (2020)
	Ti-5 vol% TiB _w /Ti ^a	541 ± 6	638 ± 7	19 ± 0.3	Liu <i>et al.</i> (2014a)
	Ti-10 vol% SiCp/Al	–	363 ± 25	24.5 ± 1.5	Fan <i>et al.</i> (2017)
	Ti-5 vol% TiB _w /Ti ^b	496	617	20.5	Liu <i>et al.</i> (2013)
	Ti-8 vol% TiB _w /Ti	552 ± 7	689 ± 7	14.1 ± 0.3	Liu <i>et al.</i> (2014b)

^aDiffusion welding.^bReaction hot pressing.

Liu *et al.*, 2014b; Monazzah *et al.*, 2013), plasticity (Duan *et al.*, 2016), toughness (Gao *et al.*, 2020), and low damage tolerance (Monazzah *et al.*, 2013). Lack of ductility and damage tolerance of MMCs can be attributed to incompatible deformation between matrix and reinforcements owing to localized strain resulting in easy crack initiation and crack propagation (Fan *et al.*, 2017). Although MMCs are used in aerospace industry, automotive industry, military, sports equipment, widespread applications are limited due to their low ductility and toughness (Gao *et al.*, 2020; Hassan *et al.*, 2004a).

On the other hand, laminate structures are an effective and useful way to improve toughness of the material (Ellis and Lewandowski, 1994; Wang *et al.*, 2018; Wu *et al.*, 2016). Miracle *et al.* (2001) reported 79% improvement in fracture toughness in LMMCs compared to its MMC counterpart. Table 1 shows the list of properties of MMCs and its LMMCs. These laminate system abets effective harnessing of superior ductility and toughness characteristic of softer/ductile material and superior strength characteristic of brittle/hard material, resulting in laminated composite with good ductility, toughness and strength (Liu *et al.*, 2014b). Miracle *et al.* (2001) termed LMMCs as smart structures. In scenarios where development of MMCs are associated with the balancing strength and ductility, LMMCs can be of great help in achieving desired properties (Hassan *et al.*, 2004a; Wang *et al.*, 2018; Wu *et al.*, 2016; Partridge *et al.*, 1996). In addition, LMMCs can also be used to achieve superior tribological properties of alloy materials. Tomida *et al.* (2001), clad aluminum alloy 5083 with thick layer of TiC/Cu metal matrix composite and achieved superior wear resistance which was six times harder than Al alloy substrate.

Processing of LMMCs

There are various processing techniques by which LMMCs can be manufactured. Few technologies from the current known methods to process laminated metal composites can be utilized to synthesize LMMCs. Like all other materials, LMMCs also show variation in properties based on manufacturing technique. Table 1 shows various mechanical properties of the LMMC materials synthesized using two different techniques. A comprehensive study on the manufacturing processes of laminated metal composite is published by Lesuer *et al.* (1996). From the literatures available, it can be inferred that not all the process mentioned in article by Lesuer *et al.* (1996) are utilized in manufacturing LMMCs. However, few processing techniques are utilized in developing LMMCs by various researchers. This section attempts to consolidate the various processing techniques used in fabrication of LMMCs and chart of the same is shown in Fig. 2.

Bonding

Bonding is a process of establishing an interatomic bond between layers of material by means of application of temperature, pressure, chemical reaction, diffusion or by use of adhesive agents. In context of LMMCs, the two layers are metal and metal matrix composite. There are various types of bonding techniques that can be employed in developing LMMCs. Based on the published research work, the bonding techniques are classified into four categories; adhesive bonding, roll bonding, diffusion bonding and reactive hot pressing. Surface treatment, bonding temperature & pressure, diffusion, chemical reactions, adhesive agents properties plays major role in mechanical and physical properties of the laminates (Lesuer *et al.*, 1996).

Adhesive bonding

Adhesive bonding is where the layer of metal and MMC are bonded at their interface by an adhesive. ARALL (Aramid Reinforced Aluminum Laminates) and GLARE (Glass Reinforced) are well known Fiber metal laminates which form the entire top of the fuselage of Airbus A3XX (Hassan *et al.*, 2004a). Successful developments of various metal laminates via adhesive bonding, persuaded researchers to investigate adhesive bonding technique to develop of metal – MMCs laminates.

Fig. 2 Various processing techniques of LMMCs.

Osman *et al.* (2008) developed aluminum based LMMCs 7093-SiC_p/7093 using epoxy as adhesive. The adhesive bonding technique displayed a strong interfacial bonding exhibiting least delamination compared to other roll bonded laminate samples (Osman *et al.*, 2008). Following the attempts made by Osman *et al.* (2008), Hassan *et al.* (2004a) also fabricated AF163–2K (3M Co) epoxy bonded aluminum based LMMCs 2080- SiC_p/2080. The monolithic aluminum and MMCs layers were degreased and etched with nitric acid followed by smearing of ABR127 primer prior to application of epoxy.

Roll bonding

Roll bonding is a process of bonding two layers of metals at their interface using rolling metal forming process as primary means to apply pressure together with heating. Depending on the temperature and plastic deformation parameters, roll bonding can be sub categorized into hot rolling, cold rolling and accumulative rolling bonding. Hot rolling and accumulative roll bonding techniques are predominantly utilized in developing LMMCs. The roll bonding process is used to manufacture plate or sheet form of LMMCs (Lesuer *et al.*, 1996).

Hot roll bonding

Hot roll bonding is commonly utilized roll bonding technique in fabricating LMMCs. Hot roll bonding is roll bonding process with application of higher temperature typically above recrystallization temperature. Fig. 3 shows the schematic diagram of roll bonding process. However, the strain in the material is lesser than accumulative roll bonding.

Hosseini Monazzah *et al.* (2014) developed aluminum based LMMCs AA1050 - SiC_p/AA6061 using hot roll bonding. In the process, the layers were heated to 475°C and at the end of five consecutive rolling, total true strain imposed on the material was 63%. Similarly, Osman *et al.* (2008) also fabricated aluminum based LMMCs 7093 - SiC_p/7093 via hot roll bonding at high temperature and realized approx. 60% thickness reduction.

Accumulative roll bonding (ARB)

Accumulative roll bonding (ARB) is a severe plastic deformation technique involving repeated rolling processes to form bonding between two materials. Typical cycle of an ARB process involves surface preparation by degreasing mechanically and chemically, stacking, rolling and cutting (Tsuji *et al.*, 1999). The process is repeated to accumulate strain in the materials there by realizing stronger bond between the layers and while realizing ultra-fine grains (Tsuji *et al.*, 1999). The process is carried under elevated temperature for better joining and workability of materials (Tsuji *et al.*, 1999). However, the operating temperature is generally maintained below recrystallization temperature, as very high temperatures result in recrystallization and cancellation of accumulated strain (Tsuji *et al.*, 1999; Saito *et al.*, 1999). Fig. 4 shows various steps of ARB process.

Chen *et al.* (2020) successfully fabricated aluminum based LMMC Al6063-(TiB₂ + TiC)_p/Al up to 3 cycles and reported strong bonding between the monolithic Al alloy and Al MMC. The developed aluminum based LMMCs exhibited superior tensile strength and ductility than (TiB₂ + TiC)_p/Al. The tensile properties of this system are listed in the Table 1.

Diffusion bonding

As defined by Everett (1991), diffusion bonding is a solid-state welding technique which can be used to join similar or dissimilar metals. An elaborate definition of diffusion bonding can also be found in the article by Shirzadi (2008). Diffusion welding,

Fig. 3 Schematic diagram showing roll bonding process. Reproduced from Khaledi, K., Rezaei, S., Wulfinghoff, S., Reese, S., 2019. Modeling of joining by plastic deformation using a bonding interface finite element. *International Journal of Solids and Structures* 160, 68–79. doi:10.1016/j.ijsolstr.2018.10.014.

Fig. 4 Schematic representation of ARB process. Reproduced from Ghalehbandi, S.M., Malaki, M., Gupta, M., 2019. Accumulative roll bonding – A review. *Applied Sciences* 9 (17), 3627. doi:10.3390/app9173627.

isostatic bonding, hot press bonding, auto-vacuum welding and thermo-compression welding are few types of diffusion bonding (Shirzadi, 2008). A deeper understanding of diffusion bonding can be attained from articles elsewhere (Everett, 1991; Shirzadi, 2008; Lee, 2012; Kazakov, 1985a,b). Fig. 5 represents a typical diffusion bonding technique used for developing LMMCs.

Hot pressing variant is most commonly reported diffusion bonding technique in synthesizing LMMCs. In an overview, diffusion bonding between two layers of metals is a result of diffusion of atoms across an interface (Lee, 2012). At first, the metal layers are cleaned from contaminations, oil and dirt chemically or mechanically. Layers of metal and MMC are stacked to form green compact. The compact is then heated under vacuum atmosphere and pressure for desirable period. In general, diffusion bonding process is carried at temperature 50%–70% of melting temperature, vacuum of 10^{-3} – 10^{-5} mbar or inert atmosphere and pressure (Shirzadi, 2008). The interfacial bonding of layers can be controlled by varying temperature, pressure and time.

Fig. 6 Schematic diagram showing reactive hot pressing process to produce LMMCs. Reproduced from Wang, S., Huang, L., An, Q., Geng, L., Liu, B., 2018. Dramatically enhanced impact toughness of two-scale laminate-network structured composites. *Materials & Design* 140, 163–171. doi:10.1016/j.matdes.2017.11.067.

Liu *et al.* (2014a,b) developed titanium based LMMCs sheets Ti-TiB_w/Ti via diffusion bonding technique under vacuum (10^{-2}). During the process, the sheets were held at 1200°C under 25 MPa pressure to develop strong interfacial bond. Smith *et al.* (1997) also successfully developed Ti based LMMCs using diffusion bonding method. Syn *et al.* (1996, 1994) developed Mg-9%Li alloy-25 vol% SiCp/Al6090 and Al5182-25 vol% SiCp/Al6090 laminates via diffusion bonding using argon gas environment.

Reactive hot pressing (RHP)

Reactive hot pressing is a process by which simultaneous chemical reaction and densification of powders takes place under the application of pressure and temperature (Chaklader, 1965; Qiang *et al.*, 2008). Since the temperature in the process is less than the sintering process and the densification of powders occur concurrently, the reactive hot pressing is considered economical, also it can be an alternative for low temperature sintering process (Qiang *et al.*, 2008; Wu *et al.*, 2008). It is noteworthy that “reactive hot pressing” is another ceramic processing technique like sintering, hot pressing or pressure fabrication (Chaklader, 1965). The RHP is extensively used to fabricate ceramic based composites (Wu *et al.*, 2008; Zhang *et al.*, 2009; Kannan and Rangaraj, 2018). A schematic diagram representing reaction hot pressing is shown in Fig. 6.

Liu *et al.* (2013, 2014c) developed titanium based LMMC Ti-TiBw/Ti by reaction hot pressing. The TiBw/Ti powders were placed on top of Ti sheets and hot pressed in vacuum (10^{-2}) at 1200°C and 25 MPa pressure for 40 min Wang *et al.* (2018) also developed titanium based LMMC Ti-TiBw/Ti via reaction hot pressing.

Powder Metallurgy

Powder metallurgy is a versatile manufacturing technique which can produce large variety of materials like alloys, composites, laminates etc. The various stages of powder metallurgy are shown in Fig. 7. The powder metallurgy utilized in developing LMMCs follows the same procedure as that of the conventional technique with a modification in the process of powder consolidation. While the powders are poured into die for powder compacting, alternative layers of the metal and MMCs are poured to form stacked layers of Metal and MMCs. Layer thickness is estimated by the mass of the powder as per Eq. (1) where A is the cross sectional area of the die, H is the height of the powder layers i.e. metal/Alloy or MMC and ρ is the density of the material.

$$\text{Mass} = A \times H \times \rho \quad (1)$$

While developing LMMCs, sintering stage in powder metallurgy might lead to various predicaments like porosity, cracking, bending, delamination and deformation in the layers due to thermal mismatch between the materials (Prikhodko *et al.*, 2020). Often the LMMCs developed through powder metallurgy process are subjected to secondary processing for further densification, to induce strain or to achieve various mechanical properties (Prikhodko *et al.*, 2020).

Duan *et al.* (2016) synthesized Ti - (TiB + La_2O_3)/Ti LMMCs using powder metallurgy followed by hot rolling to reduce porosity, grain refinement and to improved relative density from 95% to 100%.

Laser Surface Alloying Process

Laser surface alloying (LSA) is a type of laser surface treatment process, capable of producing coating, thereby enhancing resistance to corrosion, erosion, wear, oxidation or fatigue (Wong *et al.*, 2012). As defined by Wong *et al.* (2012) Laser surface alloying is a technique that involves melting of a pre-/co-deposited layer of alloying material(s) along with a part of the underlying substrate to form an alloyed zone (AZ) confined to a shallow depth from the surface within a very short interaction time. Fig. 8 shows a variant of laser alloying processing setup.

Fig. 7 Schematic diagram showing powder metallurgy process to process LMMCs (a) Metal and MMC powder stacking (b) Powder compacting (c) Billet / green compact (d) Sintering (e) Synthesized LMMC.

Fig. 8 Schematic diagram of laser surface alloying process. Reproduced from Salim, A.A., Bidin, N., Islam, S., 2017. Low power CO_2 laser modified iron/nickel alloyed pure aluminum surface: Evaluation of structural and mechanical properties. Surface and Coatings Technology 315, 24–31. doi:10.1016/j.surfcoat.2017.02.016.

Fig. 9 Schematic representation of Co-Extrusion process.

In LSA, the coating materials in the form of powders are pre placed in the cleaned, degreased substrate with or without a binder and are exposed to continuous laser beam for desired time in inert gas atmosphere. The process parameters like, laser beam's size and power, speed of scanning, exposure time, compatibility and wettability between coating powders and substrate are some important factors that need to be considered before LSA (Weng *et al.*, 2014). A consolidated study on LSA of aluminum and aluminum alloys are published by Chi *et al.* (2018) and laser cladding on titanium and titanium alloy is published by Weng *et al.* (2014).

Tomida *et al.* (2001) developed 1.5 mm thick TiC/Cu MMC layer on Al-Mg alloy A5083 and realized superior wear resistance LMMCs material with hardness six times as that of Al-Mg alloy.

Co - Extrusion

As defined by Zhao *et al.* (2019) Co-extrusion is a process in which two or more materials are concurrently extruded to form composite. Fig. 9 shows schematic diagram of co-extrusion process. The co-extrusion process is extensively used to develop dissimilar bimetallic composite materials. Researchers also successfully attempted in developing LMMCS using co-extrusion method.

Hassan *et al.* (Hassan and Lewandowski, 2009) developed Al based LMMCs of diameter 15.9 mm where powders of $Al_{89}Ni_3Gd_7Fe_1$ were co-extruded with ~2 mm thick aluminum tube as its surface. The co-extrusion reported was carried out at temperature 673K at extrusion ratio of 20:1. The sample developed shows improved damage tolerance characteristic compared to nano Al composite both in crack arrester and crack divider orientation.

Jamali *et al.* (2010) prepared ingots for co-extrusion by placing DRA (20 vol% SiCp/Al) rods in molten Al. Then the ingots were hot extruded at 400°C and at extrusion ratio 21:1 to form a rectangular bar shaped material. The fabricated material is a unique metal – metal matrix composite where SiCp/Al MMC in the form of continuous rod shape in an aluminum matrix and showed improved fracture toughness compared to SiCp/Al MMC.

Ellis and Lewandowski (1994) developed aluminum based LMMCs Al3003-SiCp/MB-85Al through co-extrusion. Toughness tests on notched and unnotched samples showed no signs of delamination due to strong interfacial bonding achieved during the process.

Spray Atomization and Deposition

Spray atomization and Deposition is a two-stage technique where molten metal in liquid state is disintegrated into micro sized droplets and are deposited to solidify on a substrate. It is also known as spray casting or spray forming (Gupta and Sharon, 2010). Fig. 10 shows the schematic diagram of spray atomization and decomposition process. Single fluid atomization and two-fluid atomization are the two ways of atomizing the molten metal (Apelian *et al.*, 2017). One of the characteristics of the LMMCs processed by spray atomization & deposition is that, no distinct separation between the two layers of metal and MMCs can be observed.

In single fluid atomization, the molten metal is forced through orifice and nozzle to form the atomization of molten metals. In the surface of the molten metal ligament from the orifice, competition between the cohesion force and perturbation force results in the wavy flow stream and with the amplified perturbation force, the liquid jet breaks to form droplets (Bogno *et al.*, 2017). The head of the molten metal before orifice and the external force plays a major role in controlling the atomization. There are various forms of single fluid atomization techniques like drop-on-demand, the pulsated orifice ejection method (POEM), the jet-splitting method, the flat-fan and pressure swirl methods, the centrifugal atomization, the ultrasonic atomization and the Impulse Atomization (IA) technique (Bogno *et al.*, 2017).

In two-fluid atomization, the jet of molten metal interacts with jet of secondary fluid to atomize the molten metal (Anderson and Achelis, 2017). The mechanism of two-fluid atomization is a complex physical phenomenon involving heat and momentum

Fig. 10 Schematic diagram representing spray atomization and deposition. Reproduced from Gupta, M., Sharon, N.M.L., 2010. Chapter – 2 Synthesis techniques for magnesium-based materials. Magnesium, Magnesium Alloys, and Magnesium Composites. John Wiley & Sons, Ltd. pp. 13–38.

transfer between the molten metal and secondary fluid (Anderson and Achelis, 2017). Free-Fall Gas Atomization (FFGA), Close-Coupled Gas Atomization (CCGA), Pressure-Swirl Film Formation Plus Gas Jet Disintegration are few other forms of the two-fluid atomization techniques (Anderson and Achelis, 2017).

Xu *et al.* (1998) fabricated layered $\text{SiC}_p/\text{6061}$ MMC using spray atomization and co-deposition. The process involved atomization of Al alloy 6061 by superheating and disintegrating into micro sized droplets using nitrogen gas as secondary fluid followed by injecting SiC_p reinforcements into the spray. Subsequently the atomized alloy and reinforcement particles are co-deposited into water cooled copper substrate. The alternative layers of Al 6061 and $\text{SiC}_p/\text{Al6061}$ were formed by varying particle/reinforcement injecting time, interval and flow rate. The developed LMMCs were subjected to secondary processing of hot isostatic pressing at 540 °C and pressure of 190 MPa for an hour before they were heat treated. No sharp interface or distinct layers of metal and MMC was observed making it significantly different LMMCs. Table 2 lists various mechanical properties, thickness ratio and process utilized in develop LMMCs.

Mechanical Behavior of LMMCs

LMMCs are formed by combination of two materials, with no reaction or limited reaction at their interfaces. The elastic properties and mechanical strengths of the LMMCs can be estimated with the help of rule of mixtures (ROM) and simple bending theory. However, researchers found that, the ductility and toughness do not follow ROM (Syn *et al.*, 1996; Gao *et al.*, 2020; Liu *et al.*, 2014b).

Mechanical Strength of LMMCs

Applicability of the rule of mixtures in estimating strength properties like the yield strength and ultimate strength of LMMCs stands with the assumption that perfect bond exists between the two layers and no slippage occurs between the layers (Shenoi, 1993). It is important to note that the LMMCs exhibit directional properties. Estimation of strength properties using rule of mixtures along longitudinal and transverse direction is described in subsequent sections.

Syn *et al.* (1996) developed dissimilar LMMCs where Mg alloy is coupled with Al based MMC and observed that, ROM holds good even for the laminates without any interdiffusion with maximum deviation in estimated strength value by about 10%. However, ductility estimation based on ROM was not in agreement with experimental value. He reported that the ductility of LMMCs is the function of ductility of interlayer region, delamination, layer thickness, hardness of individual layer and resistance for crack initiation of materials.

^aThickness ratio (thickness of metal layer to thickness of MMC).^boverall volume fraction.**Fig. 11** Laminates under longitudinal loading.

Loading in longitudinal direction

Consider a simple form of laminate with two layers stacked and bonded at its interface. When the bi-layer laminate is subjected to longitudinal axial loading i.e. loading axis is parallel to interface as shown in Fig. 11 and assuming perfect bonding between two layers, laminates exhibit iso-strain behavior upon loading. Iso-strain behavior is the state where each layer has equal strain as that of composites and loads are shared between the layers (Shenoi, 1993). Eqs. (2) and (3) represent the iso-strain condition of LMMCs.

$$\varepsilon_L = \varepsilon_{MMC} = \varepsilon_M \quad (2)$$

$$P_L = P_{MMC} + P_M \quad (3)$$

Where ε and P is strain and load, subscripts L, MMC and M represent laminates, metal matrix composite and metal/alloy respectively. Based on the Eqs. (2) and (3), the strength of the laminate composite can be derived and is called rule of mixture formulation (Shenoi, 1993). The strength of the laminate material based on ROM in terms of volume fraction is given in Eq. (4) (Wu *et al.*, 2016)

$$\sigma_L = v_{MMC} \sigma_{MMC} + v_M \sigma_M \quad (4)$$

Where $\sigma_L, \sigma_{MMC}, \sigma_M$ is strength of the laminate, MMC and monolithic metal/alloy, respectively and v_{MMC}, v_M is the volume fraction of MMC and monolithic metal/alloy, respectively. Liu *et al.* (2014b, 2013) used a generic form of rule of mixture equation to estimate LMMCs properties in terms of thickness.

$$\xi_L = \frac{\xi_{MMC} h_{MMC} + \xi_M h_M}{h_{MMC} + h_M} \quad (5)$$

Where ξ_L, ξ_{MMC} , and ξ_M are the properties like yield strength, ultimate strength and elastic modulus of laminate, MMC and metal/alloy respectively. h_{MMC}, h_M is the thickness of MMC and Metal/alloy layer respectively.

Fig. 12 Laminates under transvers loading.

Loading in transverse direction

Consider a bi-layer laminate subjected to transverse loading i.e. loading axis is perpendicular to the interface, as shown **Fig. 12**. As the cross-sectional area of the laminas are same and assuming perfect bonding at the interface, the laminate exhibit iso-stress behavior. Iso-stress is the state where laminas are subject to same stress. **Eq. (6)** represents the iso-stress condition. From **Eq. (6)**, it can be inferred that in transverse loading condition, the strength of the laminate is equal to the strength of the weakest lamina.

$$\sigma_L = \sigma_{MMC} = \sigma_M \quad (6)$$

In Titanium based LMMC, **Liu et al. (2014b)** observed that as the thickness of Ti is reduced, the theoretical estimation of strength of the laminate based on rule of mixtures was less than the experimental values. **Wu et al. (2016)** described the strength of the laminate as the linear superposition of traditional strengthening and structural strengthening as mentioned in **Eq. (7)**. Traditional strengthening was ascribed to solution strengthening, dispersion and particle strengthening of materials by the reinforcement particles and intermetallics formed between metal/alloy and MMC layers. The structural strengthening was ascribed to redistribution of stress due to load transferring at the interfaces between two layers and inhibiting strain localization thus enhancing stable deformation and damage tolerance of the material. **Wu et al. (2016)** estimated that, 22% of laminate strength is due to the structural strengthening in the developed Ti(Al)-TiBw/Ti LMMCs. **Wu et al. (2016)** asserted that synchronous deformation is impossible to occur in the laminated structure, although each layer participates in the deformation process.

$$\sigma_{laminates} = \sigma_{traditional} + \sigma_{structural} \quad (7)$$

Elastic modulus of LMMCs

Elastic modulus of the LMMCs can be estimated based on rule of mixtures and also using simple bending theory. Based on rule of mixture, elastic modulus of the laminate in longitudinal direction, assuming perfect bonding between interface and iso-strain condition, is given by (**Shenoi, 1993**):

$$E_L = \nu_{MMC} E_{MMC} + \nu_M E_M \quad (8)$$

Similarly, based on rule of mixture, elastic modulus of laminate in transverse direction, assuming perfect bonding between interface and iso-stress condition, is given by (**Shenoi, 1993**):

$$E_L = \frac{1}{\frac{\nu_{MMC}}{E_{MMC}} + \frac{\nu_M}{E_M}} \quad (9)$$

Where E_L , E_{MMC} and E_M is the elastic modulus of laminate, MMC and metal/alloy, respectively. Apart from rule of mixture, **Smith et al. (1997)** proposed utilizing simple bending theory to predict elastic modulus of LMMCs under bending. **Smith et al. (1997)** found that the estimated effective young's modulus using simple bending theory was in excellent agreement with experimental results from four-point bending test for developed Ti based LMMCs. As proposed by **Smith et al. (1997)** an effective Young's modulus in bending for the LMMCs is given by **Eq. (10)** and **Fig. 13** shows the various parameters used in bending theory analysis.

$$E_b = \frac{3}{2t^3} \frac{M}{R} \quad (10)$$

Where, E_b , $2t$, and $\frac{M}{R}$ are effective young's modulus in bending, thickness of LMMCs and bending stiffness, respectively. The bending stiffness is given by the **Eq. (11)**

$$\frac{M}{R} = \frac{2}{3} \sum_{n=1}^k E_k (z_k^3 - z_{k-1}^3) \quad (11)$$

Here, M is the bending moment per unit width b and R is the inverse curvature of the neutral axis of the beam bending stiffness, respectively. It can be noticed that the estimation of young's modulus using rule of mixture is insensitive to the stacking sequence where as simple bending theory is sensitive to stacking sequence. **Smith et al. (1997)** developed "C" and "S" types of tri-layer

Fig. 13 Schematic diagram showing various parameters of LMMCs used in bending theory analysis. Redrawn from Smith, D.J., Zuo, Y.Q., Partridge, P.G., Wisbey, A., 1997. Bend stiffness and strength of laminates composed of titanium alloy and titanium metal matrix composite. *Materials Science and Technology* 13 (1), 35–40. doi:10.1179/mst.1997.13.1.35.

Fig. 14 Diagram showing extrinsic and intrinsic toughening in materials. Reproduced from Launey, M.E., Ritchie, R.O., 2009. On the fracture toughness of advanced materials. *Advanced Materials* 21 (20), 2103–2110. doi:10.1002/adma.200803322.

LMMC, where C type laminate had MMCs as mid layer and S type had monolithic Ti Alloy as mid layer. The young's modulus estimated based on simple bending theory in S type LMMC was higher than C type LMMC.

Density of LMMCs

Density of the LMMCs can also be estimated based on the rule of mixture. The density (ρ) of the LMMCs in terms of volume fraction and thickness (Liu *et al.*, 2014b, 2013) of lamina is given Eqs. (12) and (13) respectively.

$$\rho_L = v_{MMC} \rho_{MMC} + v_M \rho_M \quad (12)$$

$$\rho_L = \frac{\rho_{MMC} h_{MMC} + \rho_M h_M}{h_{MMC} + h_M} \quad (13)$$

Fracture Mechanics of LMMCs

LMMCs outshine MMCs in ductility, resistance for crack initiation and crack propagation. There are numerous researches attempting to understand the fracture mechanics of LMMCs. This section of the article makes an attempt to summarize results of various researches to understand the phenomena of damage tolerance and enhanced toughness of LMMCs.

The increase in the toughness of the LMMCs can be attributed to intrinsic and extrinsic toughening mechanism (Liu *et al.*, 2014b; Sills and Thouless, 2015). Intrinsic toughening mechanisms occur ahead of the crack tip (Sills and Thouless, 2015). Intrinsic toughening is generally governed by the intrinsic properties like precipitates, particle spacing, grain size, particle size, particle distribution, reinforcement type, quantity of reinforcement, matrix condition, morphology etc (Liu *et al.*, 2014b; Osman *et al.*, 2008). The Intrinsic properties are related to individual material layers of LMMCs. Modification in these intrinsic properties can improve the fracture resistance of metals and MMCs (Osman *et al.*, 2008). Extrinsic toughening mechanism occurs behind the crack tip. Few phenomena of extrinsic toughening are crack bridging, stress transferring or unloading at crack wake (Sills and

Fig. 15 Schematic diagram of three-point bending and four-point bending test and their corresponding bending moment diagram and transverse force diagram. Reproduced from Volker Altstädt, A.F., 2015. Fig. 16 Schematic diagram showing: (a) Crack divider (b) Crack arrester configuration notched samples.

Thouless, 2015) leading to interfacial delamination and crack deflection (Liu *et al.*, 2014b). Fig. 14 shows intrinsic and extrinsic toughening mechanisms in material.

Generally, notched specimen is used to measure toughness of LMMCs. Three-point bending test, four-point bending test, compact testing, Charpy V-notch impact test are few tests employed by various researchers to understand the bending, fracture and impact behavior of LMMCs. One of the major differences between three-point bending and four-point bending test is in the nature of loading the specimen. In 4 point, the center portion of the specimen is subjected only to uniform bending moment. Fig. 15 shows the schematic diagram of three-point and four-point bending test.

Depending on the notch orientation or loading orientation, crack divider and crack arrester are the two configurations of test samples predominantly used to measure toughness of the LMMCs. In crack divider configuration, the loading direction is parallel to layers/interface and the notch in the sample is shared with all the layers as shown in Fig. 16(a). In crack arrester configuration, the loading direction is perpendicular to the layers/interface and the notch in the sample lies either in metal or MMC layer as shown in Fig. 16(b). Depending on the notch orientation or loading, the samples show different fracture mechanism (Osman *et al.*, 2008).

Fracture of samples with notch/loading in crack divider orientation

Osman *et al.* (1994) carried out a tensile test in a crack divider notched specimen of Al based laminate 7093–15 vol% SiC_p/7093. He observed non catastrophic failure in LMMCs against a catastrophic failure of MMC 15 vol% SiC_p/7093. They (Osman *et al.*, 1994) described the failure of the LMMCs as step wise process: (1) initiation, (2) arrest, (3) re-initiation and (4) subsequent arrest. He explained that the stable crack growth of LMMCs was due to the energy absorbed by the ductile Al7093 material at crack wake reducing energy for crack propagation. Osman *et al.* (1994) stated that the crack stability depends on the new surface formation energy and the material energy absorption. The ductile layer in the LMMCs effectively reduces the stress intensity levels at crack tip promoting stable crack growth. When the ductile layer fails, all the load concentrate near the crack tip and hence, the unstable crack growth.

Further Osman (Osman *et al.*, 2008) performed three-point bending test on crack divider notched specimen of Al based laminate 7093–15 vol% SiC_p/7093. He observed an improved toughness of the LMMCs than MMC. Apart from stable crack growth, the post-mortem analysis revealed that the extent of crack growth in MMCs was larger than Al alloy. Like in (Osman *et al.*, 1994), the stable crack growth was due to the crack bridging phenomena by the irreversible plastic deformation of ductile ligament

Fig. 17 Diagram representing Wang *et al.* explanation of fracture in LMMC. Reproduced from Wang, S., Huang, L., An, Q., Geng, L., Liu, B., 2018. Dramatically enhanced impact toughness of two-scale laminate-network structured composites. *Materials & Design* 140, 163–171. doi:10.1016/j.matdes.2017.11.067.

at the crack wake of MMCs absorbing the energy. Thus, confirming the crack bridging as the dominate mechanism in enhancing toughness of the LMMCs in crack divider configuration test specimen. Osman (Osman *et al.*, 2008) also pointed that, the delamination also improved the toughness of the LMMCs. He theorized that in crack bridging, the effectiveness of the ligament is directly proportional to the toughness of the bridge material.

Hassan *et al.* (Hassan and Lewandowski, 2009) developed nanoscale aluminum metal matrix composite sandwiched with pure Al by co-extrusion process and studied the bending ductility and fracture toughness. The nanoscale Al MMCs exhibited catastrophic failure in 3-point bending test and its LMMCs with Al had non catastrophic failure. When the test was performed in crack divider-oriented notch specimen, load drop in the load -displacement curve was observed. Later there was increase in the load carrying capacity of the material before final failure. Similar observation was also made in tri-layer LMMCs. The observation by Hassan also shows step wise fracture behavior as explained by Osman (Osman *et al.*, 1994).

Miracle *et al.* (2001) developed Al based LMMCs Al3003–15 vol% SiC_p/7093 with varying heat treatment and carried out fracture toughness test in a crack divider notched test sample. The LMMCs had 79% and 53% improvement in toughness compared to DRA (MMC) in underaged and peak-aged condition samples, respectively.

Fracture of samples with notch loading in crack arrester orientation

Wang *et al.* (2018) studied the bending and impact toughness of titanium based LMMCs in an unnotched and notched sample along crack arrester loading orientation. He also noted that, the developed LMMCs had superior toughness than its MMC counterpart. During the impact loading, the MMC took more loading than monolithic metal, resulting in breakage of whisker shaped reinforcements due to poor stress transferring reinforcement and unstable crack propagated along boundaries where local volume fraction of reinforcement was high. But in LMMCs, there is an alternative layer of metal which in general has higher toughness, is stacked between MMCs. As crack reaches the interface, metal layer offers a resistance and stops the crack propagation as metals slips and orients favoring whisker reinforcements to transfer loads effectively. Further, the impact load generates crack in the metal layer near interface which propagates in a stable fashion. Fig. 17 pictorially explains the fracture mechanics of LMMC as described by Wang *et al.* (2018). The metal layer in the LMMCs creates crack deflection and blunting resulting in enhanced toughness and ductility. However, the failure mechanism of LMMCs in crack arrester orientation is different from crack divider orientation. Impact test results of Ti-TiBw/Ti LMMCs by Wang *et al.* (2018) showed stage wise failure behavior as described by Osman *et al.* (1994).

Osman *et al.* (2008) also performed three-point bending test of Al based LMMCs with notch along crack arrester orientation. When the test samples are subjected to three-point bending test, the delamination between the notch layer and the adjacent DRA layer occurs before the crack propagates to DRA MMCs. Due to this, the triaxial stress is reduced ahead of crack tip. Once the crack reaches the delaminated region, the sample, now, behaves like an unnotched sample. The crack then initiates in the DRA MMCs and propagates rapidly. Before the crack reaches the ductile layer the delamination between the layer occurs and finally the energy absorption is associated with the monolithic material. Fig. 18 schematically represents the fracture mechanism as explained by Osman *et al.* (2008). Among the samples developed through roll bonding with foil, roll bonding and adhesive bonding, the roll bonded samples with foil exhibited highest fracture toughness and adhesive bonded laminate had least fracture toughness and was attributed to the greater degree of delamination in the roll bonded samples with foil and least by adhesive layer.

Hassan *et al.* (Hassan and Lewandowski, 2009) performed three-point bending test in crack arrester oriented notched sample of Al based LMMC. The test results showed drop in the load after some initial loading in load displacement graph, suggesting the crack initiation and rapid growth, however the sample had higher fracture toughness than MMCs due to Al layer. The fracture behavior of the sample developed by Hassan *et al.* (Hassan and Lewandowski, 2009) was similar as that of Osman *et al.* (2008). The load – deflection curve for crack arrester notched samples of Ti based LMMC samples developed by Liu *et al.* (2016) also exhibited similar results as of Osman *et al.* (2008). Liu *et al.* (2016) described it as “pop-in” fracture behavior. As the samples

Fig. 18 Schematic diagram representing fracture mechanism of crack arrester oriented notched sample in three-point bending test. Redrawn from Osman, T.M., Hassan, H.A., Lewandowski, J.J., 2008. Interface effects on the quasi-static and impact toughness of discontinuously reinforced aluminum laminates. *Metallurgical and Materials Transactions A* 39 (8), 1993–2006. doi:10.1007/s11661-008-9538-x.

developed were multilayered, the cycle of crack initiation, arrest, re-initiation and subsequent arrest continued until the final layer. Delamination, crack deflection and blunting mechanism were dominant mechanisms in improving the toughness of the LMMCs. In LMMCs, if the material satisfies the equation proposed by Osman *et al.* (2008) then crack at the interface gets deflected instead of progressing through the next layer.

$$\frac{G_{ic}}{G_{fc}} \leq \frac{h_m E_m + h_f E_f}{h_f E_f} \left(\frac{1}{4\pi(1 - \nu^2)} \right) \quad (14)$$

Here, G_{ic} and G_{fc} are the fracture energies of the interface and uncracked layer, respectively; h_m and h_f are the thickness of the cracked matrix and uncracked layer, respectively; E_m and E_f are the Young's moduli of the cracked matrix and uncracked layer, respectively and ν is Poisson's ratio.

Delamination

Delamination in the LMMCs is due to weaker interfacial bonding. Sample which exhibits minimal delamination is due to stronger interfacial bond between the layers. Stronger interfacial bonding in LMMCs offers less resistance for crack propagation at interface. Hence cracks propagate to adjacent layers with ease and cracks propagation is prevented as long as the monolithic metal/alloy layers resist it. Osman *et al.* (2008) utilizes Eq. (14) to understand the energy absorption due to delamination in LMMCs.

$$W_d = 2f\sigma_0nd \quad (14)$$

Where W_d is the energy absorbed during delamination, f , σ_0 and n is the volume fraction, flow stress and work hardening coefficient of ductile material, respectively and d is the delamination length.

Zhang and Lewandowski (1997) studied delamination in samples with crack arrester notched samples using four point bending test. They found that, the samples with higher delamination i.e., weaker interfacial strength, had higher toughness than samples with lesser delamination. However, Zhang and Lewandowski (1997) and Miracle *et al.* (2001) pointed that, the weaker interfacial strength results in weaker tensile strength highlighting the importance of interfacial strength on structural integrity. If K_I is the stress intensity factor of laminate with notch to interface distance d , then the strength of the interface is given by (Zhang and Lewandowski, 1997):

$$\sigma_f = \frac{K_I}{(2\pi d)^{0.5}} \quad (15)$$

Similar observation was made by Liu *et al.* (2016) in titanium based LMMCs Ti-TiB_w/Ti, where the crack arrester notched samples with weaker interfacial bonding had larger extent of delamination and superior fracture toughness. Wang *et al.* (2019) used ABAQUS simulation to estimate the interfacial strength in Ti based LMMCs. The interfacial bonding strength was estimated as the difference between the maximum stress estimated in the adjacent layers.

$$\sigma_{\text{interface stress difference}} = \sigma_{\text{outermost-layer-max}} - \sigma_{\text{adjacent-layer-max}} \quad (16)$$

Hence, the energy absorbed by the samples depends on the interfacial bonding properties. Osman *et al.* (2008) observed that, delamination did not change the peak loading, but had drastic improvement in the total deflection. Hence, it can be inferred that the delamination is an important phenomenon aiding toughness enhancement in LMMCs. The energy consumed by the delamination will reduce the energy available for propagation in both MMCS and Al alloy layers (Osman *et al.*, 2008). Delamination is favorable when materials are subjected to impact loading or a severe loading condition (Miracle *et al.*, 2001). The interfacial bonding on the layers are one of the vital parameters of LMMCs to achieve ductility, toughness, tensile properties and structural integrity. In a given laminate the interfacial bonding is majorly controlled by the manufacturing process.

Hosseini Monazzah *et al.* (2014) utilized shear test to determine the interfacial strength of the laminates. He developed Al based MMC Al1050-SiC_p/Al6061 via roll bonding process with varying rolling strain and volume % of SiC_p reinforcements. He found that the interfacial strength increased with increase in number of rolling pass and it decreased with increase in amount of

SiC_p reinforcement. During rolling process, due to multiple pass of rolling, the laminates will be subjected to increased rolling strain, higher pressure and also longer diffusion time (Hosseini Monazzah *et al.*, 2014). The increased rolling strain results in larger surface area contact between metal and MMC layers. This creates stronger bonding between the layers resulting in higher shear strength of the laminates. In the roll bonding process, the interfacial adhesion can be controlled by the rolling strain, as increase in rolling strain increases the interfacial adhesion (Hosseini Monazzah *et al.*, 2014; Monazzah *et al.*, 2013). Monazzah *et al.* (2013) also found that, plastic deformation and delamination are the major source of energy absorption that leads to increase in toughness and damage tolerance. Monazzah *et al.* (2013) also found that the delamination energy absorption decreased with increase in roll strain. Increase in roll strain increased the interfacial bonding, hence supporting Osman *et al.* (2008) findings: delamination energy absorbed is directly proportional to delamination length in LMMCs.

Wang *et al.* (2019) developed Ti based LMMCs with very high interfacial strength of 777 ± 52 MPa which is 90% of matrix strength via powder metallurgy technique.

Design Considerations of LMMCs

There are various parameters which influence the overall properties of LMMCs. Broadly, parameters like stacking sequence, stacking layer thickness, stacking layer materials and manufacturing processes are vital in designing the intended LMMCs. A thorough understanding on effects of various parameters on mechanical properties of the LMMCs assists while designing or deciding on LMMCs for a desired application. Subsequent section of this article makes an attempt to summarize the effects of various parameters on the LMMCs properties.

Stacking sequence

LMMCs with different stacking arrangements exhibit different material properties. Stacking sequence plays a key role in enhancing the damage tolerance and toughness of the laminated material by manipulating the crack propagation and blunting of the crack. Although there are a number of stacking arrangements possible considering various directional properties of metal and MMCs, the bi-material LMMCs fundamentally have four stacking arrangements. In case of multilayer LMMCs stacking arrangements are the combination of multiple bi-layer or tri-layer stacking sequences. Fig. 19 shows the hierarchy of stacking sequence and Fig. 20 shows the four fundamental stacking sequences.

Partridge *et al.* (1996) studied C-M-C and M-C-M configurations in Ti Based LMMC. Using the Ti alloy property, the C-M-C and M-C-M configured laminated were normalized to assign property ranking ratio. Based on the Ranking method, C-M-C configuration showed superior overall impact properties (Partridge *et al.*, 1996). Smith *et al.* (1997) proposed using simple bending theory to estimate the bending elastic modulus of the laminate which is sensitive to stacking sequence. As per proposed estimation method by Smith *et al.* (Kazakov, 1985b), farther the lamina with higher elastic modulus from the center of the laminate, higher the elastic modulus of laminate structure.

Wang *et al.* (2019) used simulation technique using ABAQUS tool and Johnson-cook material model to understand the effect of the stacking sequence of quad-layer titanium based LMMCs on bending behavior. The two quad-layer LMMCs are of sequence M-C-M-C and C-M-C-M which is basically formed by stacking two M-C and C-M stacking sequence, respectively. From the simulation and experimental results, the LMMCs with C-M stacking sequence had superior overall mechanical properties with double the bending strain and triple the toughness as compared to M-C configuration. The superior fracture toughness and

Fig. 19 Chart showing four stacking configurations.

Fig. 20 Schematic diagram of fundamental stacking configurations of LMMCs.

Fig. 21 Simulation results of three-point bending test from Wang *et al.* showing the stress in laminas of LMMCs (a) C-M-C-M configuration (b) M-C-M-C configuration. Reproduced from Wang, S., *et al.*, 2019. Regulating crack propagation in laminated metal matrix composites through architectural control. *Composites Part B: Engineering* 178, 107503. doi:10.1016/j.compositesb.2019.107503.

bending strain of C-M configuration is attributed to the crack blunting by the alloy layer (Wang *et al.*, 2019). Fig. 21 shows stacking arrangements and stress contouring of LMMCs in three-point bending test from Wang *et al.* (2019).

Stacking Layer Thickness

LMMCs are formed by stacking alternative layers of metal and MMCs basically to achieve higher toughness. The metal/alloy layer introduced in LMMCs improves the toughness majorly by crack bridging, crack blunting and deflecting. The toughness of the material depends on the thickness of the material as long as thickness is below the limit as mentioned in the Eq. (17) and toughness of the material is insensitive to thickness if the sample thickness is greater than that suggested by Eq. (17). As the thickness reduces below the value estimated from the Eq. (17), the toughness of the material K_{IQ} increases. Hence, the least toughness of the material is exhibited at plane strain condition when the thickness of the samples satisfies the Eq. (17) (Dowling, 2013).

$$t \geq 2.5 \left(\frac{K_Q}{\sigma_0} \right)^2 \quad (17)$$

The metal and MMC lamina in LMMCs can have similar or dissimilar thickness. Based on the thickness ratio (TR) i.e., thickness of metal/alloy layer to thickness of MMC, three configurations of LMMCs can exist $TR > 1$, $TR = 1$ and $TR < 1$. Liu *et al.* (2016) and Wang *et al.* (2019) reported that, if the thickness of the composite material layer satisfies the Eq. (18), the tunneling crack propagation can be suppressed.

$$t_{\text{composite layer}} \leq \frac{2\sqrt{3}K_{IC(\text{composite layer})}^2 \sigma_{s(\text{alloy layer})}}{\sigma_{\text{composite layer}}^3} \quad (18)$$

Where, $t_{\text{composite layer}}$ is the composite layer thickness, $K_{IC(\text{composite layer})}$ is the fracture toughness of the composite layer, $\sigma_{s(\text{alloy layer})}$ is the yield stress of the alloy layer and $\sigma_{(\text{composite layer})}$ stress in the composite layer.

Liu *et al.* (2014b) studied the effect of Ti layer thickness in Ti based LMMC Ti-TiBw/Ti. He developed LMMCs with TR ranging from 0.25 to 1.25. He found that with decrease in the thickness ratio, the strength of the Ti-TiBw/Ti laminate increased and ductility decreased with severe necking. Due to lack of plastic deformation zone, the fracture behavior of the laminate had ductile to brittle transition (DBT). With Increase in TR he found an effective blunting of crack tips resulting in increased resistance for crack propagation. Syn *et al.* (1996) reported that, reducing the thickness of individual layer enhances the ductility of LMMCs which is attributed to difficulty in delamination in developed Mg – Al MMC laminate.

Ellis and Lewandowski (1994) studied the effect of layer thickness on the impact toughness of DRA laminated materials. They used crack arrester notched sample with ductile layer thickness of 0.8–2 mm below the notch. They found that the LMMC absorbed energy more than the MMC regardless of the ductile layer thickness and the increase in toughness with increase in ductile layer thickness from 0.8 to 2 mm below the notch was 1/3rd of initial increment. The improvement in the toughness was attributed to the decrease in global volume percentage of reinforcement and effective crack shielding and deflection by the ductile layer.

Hassan *et al.* (2004b) studied the fatigue crack propagation in Aluminum based LMMCs Al6013–25 vol% SiCp/Al6090 (diffusion bonding) under fatigue load ratios of 0.1 and 0.3. Developed samples were thick and thin LMMCs with crack arrester notched specimens. The metal/MMC layer thickness in thick and thin LMMCs were 0.8 mm/0.64 mm ($TR = 1.25$) and 0.36 mm/0.36 mm ($TR = 1$) respectively. The LMMCs with thicker layer samples had better fatigue performance compared to thinner specimens. Along with improved fracture toughness, the LMMCs had increased fatigue threshold, and decreased Paris-law slopes showing improved fracture crack growth resistance. Hoffman and Gibeling (1995) developed Al based LMMCs Al5182–25 vol% SiCp/Al6090 through diffusion bonding. From the results Hoffman and Gibeling (1995) concluded that LMMCs had higher fatigue crack growth resistance but had lower fatigue threshold.

Stacking Layer Materials

From the earlier discussions, it is known that individual material properties define the overall property of the LMMCs. Especially, selection of ductile materials in LMMCs depends on the required lower yield strength, ductility, thickness and material availability (Miracle *et al.*, 2001). In case of dissimilar metal LMMCs, the possibility of formation of intermetallics near the interface must be accounted during the selection or design stage (Tomida *et al.*, 2001; Syn *et al.*, 1996; Wu *et al.*, 2016).

Generally, MMCs are designated based on volume percentage of reinforcement and matrix. In the LMMCs, with the introduction of the metal/alloy layers, volume fraction of reinforcement is obviously lesser than the volume fraction of reinforcement in MMC lamina. The volume fraction of reinforcement in LMMCs are also called as global volume percentage of reinforcement. Wang *et al.* (2018) found that, increase in the amount of the reinforcement increased the resistance for crack propagation and decreased the energy absorption during plastic stage. On the other hand, Duan *et al.* (2016) found that increase in the volume percentage of reinforcement from 5% to 10% increased the mechanical properties of Ti - (TiB + La₂O₃)/Ti but further increase of volume fraction of reinforcements from 10% to 15% reduced the ductility of the LMMCs.

Xu *et al.* (1998) developed a unique LMMCs where he introduced reinforcement particles in the matrix of Al alloy at different layers forming Alloy – MMC laminate. His observation was that the material portion or layers with higher volume percent of reinforcement was the site of crack initiation. Similarly, Wang *et al.* (2019) observed higher ratio of K_I/K_{IC} in MMC layers during the simulation studies in Ti based LMMCs and predicted MMC as the site of crack initiation. Fig. 21 shows the simulation results of Ti Based LMMCs (Wang *et al.*, 2019). Ellis and Lewandowski (1994) and Liu *et al.* (2013) agree to the point that the MMCs are the site of crack initiation. Toughness of MMCs can be enhanced based on the reinforcement type, size, volume fraction, and distribution (Wang *et al.*, 2019). However, details on enhancing the fracture toughness of MMC is beyond the scope of this article.

Applications

LMMCs are used in various fields like aerospace, automotive, electronic devices, military applications, etc (Ko and Jackson, 1993; Tomida *et al.*, 2001; Liu *et al.*, 2014b). Superior high temperature mechanical properties, relatively higher toughness than MMCs, higher damage tolerance and ductility are few characteristics of LMMCs. Due to these properties, LMMCs are used in hot structural applications like, hypersonic flight vehicle (Ko and Jackson, 1993).

Salzar (1999) demonstrated the feasibility of using LMMC instead of monolithic material in aircraft engine shaft using simulation technique. Apart from strength based applications, LMMCs are also used in wear based applications (Tomida *et al.*, 2001). In applications demanding high wear resistance and hardness, thin layer of coating is not suitable and thick layer of hard material is required. Tomida *et al.* (2001) developed a thick layer of the MMC on top of soft aluminum substrate using laser surface alloying forming LMMC.

As discussed earlier, LMMCs show directional properties depending on the individual material used in construction. LMMC structures offer lower thermal conductivity along thickness direction, which will be of great advantage in applications like hypersonic flights where combined thermal and mechanical stress are usual (Ko and Jackson, 1993).

LMMCs are advanced metal matrix composites and relatively new class of materials. Lack of data hinders the wide spread use of LMMCs (Salzar, 1999). Apart from improving toughness, damage tolerance and ductility, LMMCs have the potential to reduce the cost of MMCs due to introduction of low cost ductile/soft monolithic metal/alloy layer (Zuo *et al.*, 1998).

Introduction

Metal matrix composites (MMCs) are excellent suitors for application in weight critical applications owing to their high structural properties like elastic modulus, tensile strength, wear resistance, damping characteristics as compared to monolithic alloys. MMCs offer engineers value as they are especially suitable for uses requiring high-temperature stability and structural rigidity, lightweighting, and dimensional stability. The contemporary tendency is in the direction of safe application of the MMC parts in high pressure and temperature environments in aerospace and automobile engines. The development of MMCs reinforced with ceramic particles is a result of increased demand for stiff, strong, and lightweight materials.

High-performance lightweight cost-effective MMCs are gaining great importance in both structural and non-structural applications (Rohatgi, 1991; Kelly, 2006). MMCs studies have shown to have a significant improvement in properties and hence its potential application as compared to their monolithic counterpart. These MMCs can be specially designed to show high durability, ductility, tensile modulus, thermal conductivity, etc (Staiger *et al.*, 2006; Rawal, 2001; Shelley *et al.*, 2001). To improve its widespread acceptance in electronics, aerospace, robotics, and medical applications, special features can be incorporated in the design and development of MMCs (Ajayan *et al.*, 1993). Since the 1960s, the development of high strength carbon fibers resulted in their usage in missile conical tips, conical exit parts of the rocket, heat shields, etc. The commercial society, for the first time, noticed the importance of lightweight components exhibiting high strength properties for structural and non-structural applications as opposed to conventional alloys (Thostenson *et al.*, 2001).

The commitment by the world towards improving the sustainability of society is well documented by the Paris agreement (2015) in efforts to work towards arresting the catastrophes of climate change by reducing carbon dioxide emissions by 2 billion tons at the end of 2025 (Gupta and Gupta, 2017). To constantly innovate towards a sustainable future, as materials scientists, it is imperative to move towards making the process eco-friendly. MMCs need to be developed such that the materials find applications in cross-themed sectors like aerospace, automotive and biomedical sectors alike. Eco-friendly metal matrix composites can be realized by:

- (1) Using low-cost energy-efficient materials with high performance and widerpread applications
- (2) Using low-cost processing technology to fabricate these materials at a high volume scale
- (3) A combination of both.

In this article, the emphasis is on discussing the efforts of the research community so far in developing high-performance eco-friendly metal matrix composites. Aluminum and rare earth matrix composites are not discussed in this article as lately, several studies have reported that Al is neurotoxic, and the REs have been found to cause latent toxicity and several other harmful effects on the human body (Parande *et al.*, 2018b). Hence, substituting or reducing these elements with appropriate cost-effective bio-compatible elements and reinforcements is a sustainable option. Composites developed with zinc, titanium, and magnesium-based matrix are discussed in this article. The processing technologies commonly used in developing such composites are also briefly discussed. Mechanical, microstructural, corrosion, and tribological properties of the composites are summarized.

Processing Technologies for Eco-friendly Metal Matrix Composites

To process high-performance metal matrix composites effectively, the selection of efficient processing parameters is rendered highly valuable. The processing technologies are broadly classified into solid-state processing and liquid-state processing. In this section, the authors discuss the different methods of synthesizing eco-friendly metal matrix composites.

Solid-State Processing

Powder metallurgy: The powder metallurgy technique usually involves blending and/or mechanical alloying of the raw material powders in the required composition (Fig. 1). The matrix and reinforcements are mixed in the right amounts and the reinforcements are blended using a blender or high energy ball milling. The blended powders are then uniaxially compacted into green compacts. These green compacts exhibit a relative density of ~80%. Densification of these green compacts is done by sintering. Sintering can be performed using conventional sintering, resistance sintering, or microwave sintering (Gupta and Leong, 2008). Mechanical alloying is capable of synthesizing a variety of high strength equilibrium and non-equilibrium alloys due to the high dislocation density and homogenous distribution of reinforcing constituents.

Additive manufacturing: Additive manufacturing (AM) is used to create parts layer-by-layer. It is also called 3D printing, rapid manufacturing or rapid prototyping, or solid freeform fabrication. This technique enables the development of highly complex and

Fig. 1 Schematic of the process for preform fabrication by the powder metallurgy process. Reproduced from Kerns, J., 2016. Powder-metallurgy processes. Machine design, pp. 1–5.

intricate physical shapes and sizes assisted by Computer-Aided Design (CAD) systems. The model generated using CAD software is sliced into many layers with every layer defined by layer thickness and the object is built in a layer-by-layer fashion. Additive manufacturing technology to synthesize magnesium-based alloys and composites has gained high notice in the last 5–7 years. Some of the techniques used to develop metal-based alloys and composites are: (1) selective laser melting, (2) inkjet printing, (3) laser sintering, (4) laser powder deposition, (5) electron beam melting, and (6) wire-based additive manufacturing (Salehi *et al.*, 2018). Although AM offers an exciting avenue to develop novel metallic materials, the strength properties reported by these parts are still lower than commercially used alloys. Hence, a high level of optimization is required to make these components more viable.

Following the primary processing as mentioned above, the composites can be subjected to several secondary processing routes such as extrusion, rolling, or forging (Tekumalla *et al.*, 2016; Itoi *et al.*, 2008; Malaki *et al.*, 2019) to further consolidate or shape the composite materials to tailor them as per the requirement. Schematic of a powder bed additive manufacturing process can be seen below in Fig. 2.

Liquid State Processing

Sand casting: Sand casting is a commonly used liquid processing method to develop metal-based components and parts. The material to be cast is processed by pouring the molten slurry into a sand mold cavity. On cooling the mold, the slurry solidifies, and the cast material is released from the mold. In order to achieve high-quality cast products, it is important to reduce the mold-molten metal reactions as some metals like magnesium are highly reactive at elevated temperatures and may react with the sand (Avedesian and Baker, 1999). This can be achieved by (1) reducing the content of moisture in the sand and (2) incorporating suitable inhibitors like sulfur, potassium fluoroborate, boric acid, individually or in combination, to make the core and the molds.

Die casting: Die casting is also known as high-pressure die casting. During this process, the molten slurry is channeled through a narrow gate to fill up the mold cavity at an expedited rate (Malaki *et al.*, 2019). During solidification, a significant high pressure in the range of 40–1000 MPa is applied to the melt. This is to ensure no gas entrapments and melt is compressed and shrinkage of the metal part is reduced. The cast part solidifies at a very high cooling rate (10–1000°C/s) resulting in a refined microstructure. Die casting is commonly used for producing near net-shaped products. A schematic of the low-pressure die casting (LPDC) setup is shown in Fig. 3.

Microstructure, Mechanical Properties and Wear Behavior of the Rheoformed 2024 Aluminum Matrix Composite Component Reinforced by Al_2O_3 Nanoparticles, *Metals* 8 (6), 460.

Squeeze casting: Squeeze casting is a combination of the casting and forging processes as shown in Fig. 4. There are two types of squeeze casting namely: (1) direct squeeze casting and (2) indirect squeeze casting.

Direct squeeze casting, also known as a metal forging (Gupta and Ling, 2011), is a process when the molten slurry is poured into the lower half of the die and the upper die is lowered to complete the die set. The metallic slurry solidifies under the action of high unidirectional pressure to form the cast ingot. This technology is widely used for the processing of metal matrix composites, mainly particle reinforced metal matrix composites.

Indirect squeeze casting, though similar to direct type, but has huge similarity to the die casting method wherein the molten metal is introduced into the sleeve of the squeeze casting equipment. By optimizing the speed of the plunger, the speed at which the molten slurry is filled in the die can be manipulated. In order to achieve high dense castings, the filling speed of the molten slurry must be controlled to circumvent any turbulent flow. This method is suitable to produce metal matrix composites although the material yield in this type is not as high as the direct type.

Stir casting: Stir casting is a three-step process that involves (Malaki *et al.*, 2019): (1) melting of the matrix material, (2) incorporation of the alloying element/secondary reinforcement into the molten metal, and (3) optimized stirring to achieve uniform distribution of the reinforcements in the matrix (Fig. 5(a)). This molten slurry is then transferred to a casting setup like sand/die/mold casting. Stir casting is traditionally used for materials with a high volume of secondary reinforcements (10%–30%).

Spray forming: Spray forming is a technique also known as spray atomization and deposition or spray casting or Osprey process (Gupta and Ling, 2011). It is used to produce near net-shaped parts. In this process, the pure metal or alloy is melted in a resistance/induction furnace. The reinforcement is added either inside or outside the crucible into the molten spray. The melt/slurry is homogenized to achieve uniform distribution of secondary phases before pouring. An agitator in the form of a mechanical stirrer is sometimes used for mixing. The molten slurry/melt is then released as a free-falling stream and impacted by high energy inter gas or water jets thereby atomizing the melt onto the substrate and a preform is developed.

Fig. 6 Schematic representation of the DMD setup. Reproduced from Malaki, M., Xu, W., Kasar, A.K., 2019. Advanced Metal Matrix Nanocomposites, *Metals* 9 (3), 330.

Semi-solid casting: SSM casting is also known as thixomolding, rheocasting, thixocasting, or thixoforming (Fig. 5(b)). The thixomolding process is similar to plastic injection molding. The raw material is heated to a temperature just below the melting point under a protective argon atmosphere. Heating is done by a rotating screw and hence forms the slurry. This molten slurry is injected into the die at higher speeds to obtain the cast part. Rheocasting is a process where the raw material is heated in a mushy zone followed by die casting. In the case of metal matrix composites, reinforcements are added at the semi-solid temperature, the molten slurry is stirred, and the part is die-casted.

Melt infiltration: This process involves the infiltration of molten metal or alloy in a preform in either absence or presence of external pressure. Preparation of reinforcement into porous preform follows the injection of molten metal into the reinforcement preform (Sravva, 2018). The metal infiltrates through the open pores of the reinforcement to form a composite. Pressurized infiltration involves the application of some pressurizing medium such as gas or mechanical device. Controlling appropriate pressure during injection is important as relatively higher pressures can damage the reinforcement. This process can also be used to produce composites containing a higher volume fraction of reinforcements (40%–50%). Some of the limitations are the damage of reinforcements due to higher injection pressure, microstructural coarsening, and the formation of interfacial reaction products.

Disintegrated melt deposition: Disintegrated melt deposition (DMD) technique was developed in the early 1990s. A schematic diagram of the DMD technique representative of its actual setup developed at the National University of Singapore is shown in Fig. 6 (Gupta and Wong, 2015). DMD is a unique technique that brings together the cost-effectiveness associated with the conventional casting process and the scientific innovativeness and technological potential associated with the spray forming process. However, unlike spray forming, the DMD technique uses low to moderate superheat temperatures and lower impinging gas jet velocity. Within a graphite crucible, the metal along with alloying elements or reinforcements are superheated to 750°C under an argon gas atmosphere using a resistance heating furnace. For achieving a homogeneous metal matrix, the superheated slurry is stirred at 465 rpm for 5–10 min using a twin-blade with a pitch of 45°. ZIRTEX 25 (86% ZrO₂, 8.8% Y₂O₃, 3.6% SiO₂, 1.2% K₂O and Na₂O, and 0.3% trace inorganic) coating is applied on the stirrer to avoid iron contamination of the molten metal. After stirring, the molten metal is bottom poured into the mold, under the influence of gravity, through a 10 mm hole in the crucible. Before entering the mold, the molten metal is disintegrated by two jets of argon gas oriented normal to the melt stream.

The flow rate of argon is maintained at 25 l/min and an ingot of 40 mm diameter (variable and as required) is normally obtained. The ingot obtained is then machined to the desired length as required by the secondary processing method.

Properties for Eco-friendly Metal Matrix Composites

In this section, the microstructure and various properties like mechanical, tribological and corrosion properties of the eco-friendly metal matrix composites are discussed. The discussion is segregated based on the matrix (Zn, Ti, and Mg) and the reported advancements in the literature are highlighted.

Zinc Matrix Composites

Zinc casting alloys are versatile engineering materials. They provide an attractive combination of toughness, rigidity, strength, economical castability, and bearing and sliding wear performance. Also, zinc alloys can be synthesized at lower costs and lower casting temperatures (Owoeye *et al.*, 2019). Zinc plays an important role as a structural protein component, enzymatic cofactor, and is a vital trace element for human health acting as a transcriptional regulator in a wide range of cellular and biochemical activities (Solomons, 2013). More notably, zinc is engaged significantly in bone formation and resorption. The research on Zn being used as a potential orthopedic implant had not been reported in the literature until recently. It was recently reported in a study that the degradation rate of pure Zn is slow; it may take more than a decade for a 5 mm diameter pure Zn screw to degrade completely under bone environments (Yang *et al.*, 2018). Zinc-based composites with high mechanical strength and enhanced corrosion resistance are important for their widespread use in the orthopedic sector.

Zinc–aluminum (ZA) alloys can provide energy and economically conscious alternatives for a range of ferrous and non-ferrous alloys due to their excellent wear resistance, lower casting temperature, high strength, and abundant ability (Owoeye *et al.*, 2019).

ZA-27 alloy containing 26%–28% Al, 2%–2.5% Cu, and 0.01%–0.02% Mg was initially developed as a high strength gravity casting alloy and is widely being exploited as materials for bushings and bearings operating at low-speeds and high loads, primarily in drive trains, automobiles, wear plates and thrust washers (Sharma *et al.*, 1998). Hard secondary phases/reinforcements, such as alumina (Al_2O_3), silicon carbide (SiC), graphite, and zirconia (ZrO_2) have been effectively used as a whole or to form a hybrid, resulting in a massive property augmentation to improve the hardness, elastic modulus, strength, and wear resistance of ZA-27 alloy. However, properties like machinability, damping capacity, corrosion resistance, impact resistance, and fracture toughness (Owoeye *et al.*, 2019). However, due to the modern endeavors geared towards designing low-cost high-performance metal matrix composites, industrial waste particles and agro-waste ashes (Alaneme *et al.*, 2013; Madakson *et al.*, 2012) have been used as reinforcement to supplement either in part or wholly instead of high-cost synthetic reinforcement materials, such as SiC and alumina in ZA-27 composites (Fatile *et al.*, 2015; Folorunso and Owoeye, 2019; Almomani *et al.*, 2017; Miloradovic and Stojanovic, 2013; Kiran *et al.*, 2013; Alaneme and Ajayi, 2017).

Microstructure

Several authors in recent years, the microstructural characteristics of ZA-27 MMCs with synthetic ceramics dispersoids in combination with agro or industrial wastes have been explored and published (Fatile *et al.*, 2015; Folorunso and Owoeye, 2019; Almomani *et al.*, 2017; Miloradovic and Stojanovic, 2013; Kiran *et al.*, 2013; Alaneme and Ajayi, 2017). As stated by these studies, monolithic ZA-27 alloy is typically characterized by a dendritic pattern (a feathery feature) displaying the solidification pattern and grain morphology and composed of dendrites of primary Al-rich phase (α , FCC) generally designated by a white pattern and an inter-dendritic zinc-rich phase (η , HCP) ordinarily showed by the dark area, while the zone surrounding the α -phase is a combination of $\alpha + \eta$ area (Figs. 7–8). Although, in the case of most ZA-27 MMCs, the secondary phase particles have been described to show high interfacial integrity with the matrix despite high thermal expansion coefficient mismatch leading to high residual thermal stresses. Further, the uniform distribution of the reinforcement phase is observed in the metal matrix with limited agglomerations.

Mechanical properties

BhaskarRaju *et al.* (2017) studied the mechanical properties of ZA-27 reinforced with (0, 3, 6, and 9 wt%) SiC and reported a substantial improvement in the hardness, impact strength, compressive strength, and tensile strength of the ZA-27/SiCp composites with progressive addition of SiC.

Dalmis *et al.* (2016) investigated the effect of graphite (Gr) nanoparticles on the mechanical and physical properties of ZA-27 alloy. The authors concluded that the tensile strength and hardness decreased with the increased presence of Gr content in the alloy. This behavior was attributed to poor wettability between the ZA-27 matrix alloy and Gr particles.

Ranganath *et al.* (Owoeye *et al.*, 2019) studied mechanical properties and fracture characteristics of ZA-27/TiO₂ MMCs containing particles in the range from 0 to 6 wt% and showed significant improvements in hardness, yield strength, ultimate tensile strength, and elastic modulus albeit at the expense of fracture strain properties.

Fig. 7 (a) Representative micrograph showing: (a) unreinforced ZA-27 alloy (b) 100% SiC_p reinforced ZA-27, (c) 50% QD: 50% SiC_p hybrid ZA-27, (d) 75% QD: 25% SiC_p hybrid ZA-27. Reproduced from Folorunso, D.O., Owoeye, S.S., 2019. Influence of quarry dust-silicon carbide weight percentage on the mechanical properties and tribological behavior of stir cast ZA-27 alloy based hybrid composites. *Journal of King Saud University-Engineering Sciences* 31 (3), 280–285.

Sharma *et al.* (1996) studied the impacts of short glass fibers (0–5 wt%) on the mechanical response of cast ZA-27 alloy composites and reported a significant improvement in the elastic modulus, hardness, and the ultimate tensile strength an increased amount of reinforcement. However, the impact resistance and tensile ductility showed adverse behavior.

Alaneme *et al.* (2016) studied the wear and mechanical behavior of (5, 7.5, and 10 wt%) steel chips reinforced ZA-27 composites. It was stated that the composites displayed improved hardness and wear resistance with the increased addition of the steel chips from 5 to 10 wt%. However, a strength decrement was observed to a non-uniform dispersion and agglomeration of steel chips above 5 wt%.

Kiran *et al.* (2013) studied the mechanical properties of ZA-27/3Gr/(0–9 wt%)SiC_p hybrid composites for bearing applications. It was concluded that increased SiC_p content improved the ultimate tensile strength (UTS) of the composites. Also, noticeable enhancements were observed in the ultimate strength with the incorporation of 9 wt% SiC_p to ZA-27 (Fig. 9). The tensile strength and hardness enhanced by 11.2% with the presence of SiC_p from 0 to 5 wt% with observable decreased ductility properties.

Davies *et al.* (Folorunso and Owoeye, 2019) probed the effect of hybrid silicon carbide (SiC_p)-quarry dust (QD) on the strength and wear response of ZA-27-alloy containing 8 and 10 wt% QD-SiC_p with a varying amount of quarry dust (QD) from 0%, 25%, 50%, 75%, 100%, respectively. It was concluded that the tensile strength and hardness of the composites increased indicating a like trend as QD increased to the highest addition of 75% for both 8 and 10 wt% composites. Improved wear characteristics were observed for hybrid composites in comparison with the ZA-27-alloy with the presence of both SiC_p compositions.

Alaneme *et al.* (2014) studied the tensile and corrosion properties of Zn-27Al-based composites reinforced with silicon carbide (SiC_p) and bamboo leaf ash (BLA) containing 7 and 10 wt% BLA-SiC_p with wide-ranging amounts of 0%, 20%, 30%, and 40% BLA content, respectively. It was concluded that the tensile properties and hardness decreased with an increase in the wt% of BLA with no effect on ductility (Table 1). The reduction in hardness and tensile strength properties can be attributed to the presence of SiO₂ in BLA, which is known to be softer than SiC_p.

Kubásek *et al.* (2019) synthesized 5 wt% Mg containing Zn-Mg composite was synthesized using powder metallurgy and hot extrusion process. The presence of Mg in Zn improved the yield and ultimate strengths in both tensile and compressive modes significantly. The elongation under tensile mode however decreased from 35% to 16%.

Li *et al.* (Li, 2014) synthesized in-situ TiB₂ particles reinforced ZA27 and studied the effect on the hardness and tensile strength response. The presence of 2 wt% TiB₂ improved the ultimate tensile strength from 393 to 489 MPa, respectively. The Brinell hardness measurement also improved from 116 to 157 kgf/mm², respectively. Homogenous distribution of in-situ formed TiB₂

Fig. 8 Representative SEM images showing: (a) unreinforced ZA-27 alloy (b) 100% SiC_p reinforced ZA-27, (c) 50%QD: 50% SiC_p hybrid composite. Reproduced from Folorunso, D.O., Owoeye, S.S., 2019. Influence of quarry dust-silicon carbide weight percentage on the mechanical properties and tribological behavior of stir cast ZA-27 alloy based hybrid composites. *Journal of King Saud University-Engineering Sciences* 31 (3), 280–285.

particles was observed in the interdendritic regions between the primary α -Al dendrites in ZA27 alloy. The primary α -Al and η -Zn phase morphology and the amount of eutectoid structure varied considerably with the presence of TiB₂ particles.

Corrosion properties

Corrosion behavior of the ZA-27 alloy has been recently investigated by researchers (Barnhurst and Beliste, 1992; Porter, 1994). The ZA-27 alloy displays high corrosion resistance in natural atmospheres, soil, and waters, etc. as an effect of the capability of zinc to form protective oxide and hydroxide layers or their mixtures on the surface (Barnhurst and Beliste, 1992; Porter, 1994). However, more recently, several authors have studied and reported the effect of reinforcement particles on the corrosion characteristics of ZA-27 alloy (Almomani *et al.*, 2017; Alaneme *et al.*, 2014; Sharma *et al.*, 2001; Seah *et al.*, 1997; Pathak and Pandey, 2020).

Mohammed *et al.* (Almomani *et al.*, 2017) studied the corrosion behavior of Al₂O₃ and fly ash reinforced ZA-27 alloy in 3.5 wt% NaCl solution using direct current polarization test. It was reported that reinforcing ZA-27 alloy by Al₂O₃ and fly ash particles decrease its corrosion resistance. This behavior was attributed to the micro-galvanic corrosion occurring at the reinforcement level in the matrix.

Alaneme *et al.* (2014) also investigated the effect of silicon carbide (SiC_p) and bamboo leaf ash (BLA) on the corrosion behavior of ZA-27 alloy by immersion method in solutions of 0.3 M H₂SO₄ and 3.5 wt% NaCl. The presence of BLA-SiC_p in ZA-27 alloy realized a very stable response in 3.5 wt% NaCl solution and the corrosion resistance in 0.3 M H₂SO₄ solution was superior to that of the single SiC_p reinforced ZA-27 composite grade.

Fig. 9 Variation of (a) UTS, (b) elongation, and (c) hardness of ZA-27/3Gr material for different percentages of SiCp. Reproduced from Kiran, T., Kumar, M.P., Basavarajappa, S., Vishwanatha, B., 2013. Mechanical properties of as-cast za-27/gr/sicp hybrid composite for the application of journal bearing. *Journal of Engineering Science and Technology* 8 (5), 557-565.

Sharma *et al.* (2001) studied the effects of (1–5 wt%) particles on the corrosion characteristics of ZA-27 alloy in the HCl solution at room temperature using a conventional weight-loss method. It was concluded that the corrosion protection of the composites was enhanced with the progressive content of ZrSiO₄ particles. However, it was noted that the rate of corrosion was high owing to the pit formation ZA-27 alloy surface. However, in the composites, the pit formation occurred at the ZrSiO₄/ZA-27 interface.

Sharma *et al.* (Seah *et al.*, 1997) evaluated the corrosion characteristics of ZA-27/glass fibers in the HCl solution and observed that the higher the amount of glass fibers in the ZA-27 alloy, the higher is the corrosion protection. This is attributed to the inertness of the glass fibers. The chloride solution although destabilizes the formation of a protective layer due to the presence of active chloride ions causing anodic dissolution.

Pathak *et al.* (Pathak and Pandey, 2020) synthesized Fe containing Zn-based HAP composites and studied the corrosion and biocompatibility behavior of the materials. The progressive addition of HAP along with Fe in the Zn matrix leads to reduced

corrosion protection owing to the pit formation on the surface and micro galvanic corrosion. The cell viability studies of these composites displayed elongated shape of the cells revealed that the Zn based composites are highly non-toxic. The highest cell viability was observed in Zn-3HAP samples from indirect cytotoxicity evaluation.

Titanium Matrix Composites

Titanium and its alloys are rapidly becoming of substantial research importance for a broad range of products in the aerospace, automotive, and defense industries. These lightweight materials are lightweight to have salient properties such as excellent chemical resistance, high specific strength, and excellent biocompatibility. The holistic blend of these properties makes Ti-based alloys a viable option for chemical, marine, petrochemical, structural, and biomedical applications (Welsch *et al.*, 1993; Hayat *et al.*, 2019). However, the high-temperature resistance, wear-resistance, and elastic modulus of Ti-based materials are inferior to those of ferrous and Ni-based alloys (Li *et al.*, 2013; Kuzumaki *et al.*, 2000). Titanium metal matrix composites (TMMCs) provide an alternative to overcome these shortcomings.

The introduction of TMMCs into high-performance commercial sectors has not been forthright owing to the various complications involved in the design and development associated with high raw material and operating costs. Even so, steady attempts have been made by various researchers, particularly by the National Aeronautics and Space Administration (NASA), to improve their applicability for industrial usage. Among many success stories associated with TMMCs, the formation of the Titanium Matrix Composite Turbine Engine Composite Consortium (TMCTECC) program was a great attempt, where six US corporations collaborated for the design, development, and application of TMMCs into large gas turbine engines (Singerman *et al.*, 1996; Anderson, 1998).

In the titanium metal matrix composite technology, ceramic particles such as ZrC, TiB, TiB₂, B₄C, TiC, TiN, SiC, CNTs, and Al₂O₃. Among these TiB and TiC are most widely utilized (Geng *et al.*, 2008; Morsi and Patel, 2007). Apart from TiB and TiC, other reinforcements such as Si₃N₄ (Dougherty *et al.*, 2016), SiC (Sivakumar *et al.*, 2017), Al₂O₃ (Shivakumar *et al.*, 2015), and CNTs (Munir *et al.*, 2015) have also been reported in the public domain. A few interesting results are discussed in this section.

Mechanical properties

If the intrinsic properties of the matrix and the reinforcement are known, the stiffness and strength properties of the composites can be predicted in the longitudinal direction by the rule of mixtures, generally for the fiber-reinforced composites. The tensile strengths of TMMCs containing SiC reinforcement have been evaluated by some researchers fabricated by various processing methods. The effect of varying amounts of SiC fibers has also been studied (MacKay *et al.*, 1991; Pank and Jackson, 1993; Lobley and Guo, 1999; Leyens *et al.*, 2003; Leucht and Dudek, 1994).

Cui *et al.* (2018) studied graphene coated carbon fibers reinforced TiAl alloy composite fabricated by melt-spun, powder metallurgy, and vacuum melting. The work concluded that the composites showed excellent mechanical response with a hardness, fracture strain, and strength value of 426 HV, 26.27%, and 2312 MPa, respectively. It can be predicted that this methodology opens up novel prospects to synthesize TMMCs containing fibers in a simple yet unique manner.

According to the work in the public domain (Geng *et al.*, 2008; Morsi and Patel, 2007), in-situ synthesized TiC particulates (TiCp) and TiB whiskers (TiBw) and are known to be the effective reinforcements for directionally reinforced titanium composites (DRTC). This is owing to their similar density and thermal expansion coefficients and good chemical compatibility with titanium, high hardness, and high modulus. DRTCs display higher tensile properties than unreinforced Ti alloys over a range of temperatures. The ultimate tensile strength is increased owing to the distribution of fine whiskers and particulates leading to the dispersion-strengthening and hardening. The reinforcements restrict the dislocation movement, also known as the Orowan strengthening mechanism. In comparison with the precipitation hardening, the reinforcements added ex-situ added are observably stable at higher temperatures.

Recent articles in the literature (Chaudhari and Bauri, 2018; Choi and Kim, 2013; Kim *et al.*, 2011) suggest using different combinations of secondary reinforcements to realize the cumulative effects of individual reinforcements. Liu *et al.* (2015) designed and developed Ti64 alloy reinforced with Ti₃SiC₂ bar, ultrafine Ti₅Si₃ needle, and in-situ TiC particle composites. The study observed a tailored distribution of the secondary reinforcements. This was possible with larger sized matrix powders and smaller sized secondary reinforcement powders using low-energy milling, and an in-situ hot pressing process. In comparison with monolithic Ti64 alloy, the (Ti₃SiC₂ + Ti₅Si₃ + TiC)/Ti64 composites displayed an excellent combination of mechanical strength and fracture strain. The composites containing 5.0 vol% reinforcements with 0.5 μm-sized SiC displayed a UTS and fracture strain of 1171 MPa and 5.3%, respectively. This improvement in properties was attributed to the solid solution strengthening effect, strengthening due to the presence of hybrid reinforcements, a tailored network structure and, the large area of the Ti64 matrix. Table 2 provides a summary of the titanium matrix eco-friendly composites based on mechanical properties.

Tribological properties

Another area where discontinuously reinforced titanium matrix composites are the ideal option over composites containing fibers are applications requiring higher wear resistance. However, owing to their low hardness, Ti and its composites are generally considered not the preferred choice for wear-resistant applications. The presence and progressive addition of hard ceramics in the

form of particles, whiskers, or fibers in a ductile Ti matrix can enhance the hardness significantly enhances its hardness and hence the wear resistance of the Ti matrix. Although, fiber-containing titanium composites have rarely been preferred for wear-resistant applications owing to their anisotropic properties and high cost.

Several researchers have studied the sliding wear response of titanium matrix composites (Kim *et al.*, 2011; Zi-Run *et al.*, 2017; Kang *et al.*, 2016; Kim *et al.*, 2013; Singh *et al.*, 2019; Attar *et al.*, 2017). Kim *et al.* (2011) studied the effect of (TiB + TiC) on the wear and friction response of titanium matrix. Further, with the addition of B₄C particles to commercially pure (CP) Ti used vacuum induction melting to synthesize TMMCs. It was They established that the presence of 20% content of the secondary reinforcement is the most preferred way to enhance the wear and friction behavior. It was also concluded that the wear behavior of the Ti matrix improved with the progressive addition of the reinforcement.

An *et al.* (2018) effectively synthesized in-situ TiBw/Ti64 composites using the powder metallurgical process comprising a network structure. It was concluded that the TiBw network structure boundary comprehensively resisted abrasive wear. This was attributed to the network boundary acting as a barrier resulting in improved hardness and sliding wear characteristics of the Ti64 alloy. Further, it was observed that the size of the network closely influenced the wear properties and the mechanism. The friction coefficient and wear loss increased from 0.164 to 0.188 and 4.654 mg to 6.110 mg, respectively, and concluded that the presence of 8.5 vol% TiBw exhibited the highest wear resistance for a network size of 60 μ m. The wear mechanism observed was micro-cutting and brittle debonding with the increment in the size of the network from 60 to 200 μ m, respectively.

Biocompatibility

In recent studies, TMMCs are gaining immense attention as a potential biomaterial especially in the field of orthopedic implants and devices (Comín *et al.*, 2017; Kumar *et al.*, 2013b; Chu *et al.*, 2006; Chen *et al.*, 2017). HA ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) is a bioceramic used for hard tissue implants in human applications. Its chemical and crystallographic structure is very comparable to the natural bone (Weiner and Wagner, 1998). The presence of hydroxyapatite (HA) in the titanium matrix has been increasingly studied for biomedical properties to establish its suitability. The Ti-HA composites resulted in a beneficial arrangement of HA for the biocompatibility and strength properties of titanium. Further, HA is bioactive, nontoxic, and biocompatible resulting in higher osseointegration between the bones and the implants (Ong and Chan, 2000). However, a major limitation of using HA on its own is its limited load-bearing capacity. In contrast, Ti has a higher load-bearing capacity, high biocompatibility, and low cytotoxicity. As a result, Ti-HA composites have been believed to have a promising material for orthopedic applications.

The easiest way to synthesize Ti-HA composites is by solid-state processing namely powder metallurgy process (Ning and Zhou, 2008; Comin *et al.*, 2013). Powder metallurgy uses Ti and HA powders to develop high-performance sintered composites wherein the HA particles are uniformly distributed within the Ti matrix. Recently, the FAST (field-assisted sintering technique) has been effectively utilized to synthesize near dense composites at lower energy costs and time frames (Kumar *et al.*, 2013a). Furthermore, studies on synthesizing such composites with biocompatible properties have also been reported using the additive manufacturing process (Qian *et al.*, 2015).

Magnesium Matrix Composites

Magnesium (Mg) is the sixth most abundant element making up $\sim 2.7\%$ by weight of the earth's crust. Mg is the lightest structural element with a density of 1.74 g cm^{-3} is $\sim 35\%$ and $\sim 77\%$ lighter than that of aluminum and steel, respectively (Gupta and Sharon, 2011). In addition to its lightweight, Mg-based materials exhibit enhanced mechanical, thermal, and damping properties, good castability, machinability, and superior resistance to electromagnetic radiation (Itoi *et al.*, 2008; Nguyen *et al.*, 2009; Meenashisundaram and Gupta, 2016). In the past decade, the potential for Mg as a "biomaterial" has encouraged a lot of research with a noticeable increase in the number of scientific publications investigating novel magnesium alloys and composites containing biocompatible reinforcements (Farraro *et al.*, 2014). Mg exhibits superior biocompatibility, shows no indications of local or systemic toxicity (Staiger *et al.*, 2006; Sietsema, 1995; Ramirez and Hurt, 1977), and is the second most abundant intracellular cation being essential for body metabolism (Martin and Preedy, 2014; Xin *et al.*, 2011). With an elastic modulus closer to the natural bone, Mg-based materials when used as an implant material in orthopedic applications can be successful in mitigating stress-shielding effects and possibly eliminate further corrective procedures.

However, the limited ductility of Mg at room temperature and low wet corrosion resistance restricts its usage in many applications. For enhancement of mechanical properties of Mg materials, the addition of inexpensive low volume fraction nanoparticulates (NPs) resulting in dispersion strengthening can be a valid approach when compared to grain refinement achieved by alloying (Umeda *et al.*, 2010). The selection of reinforcements for magnesium composite technology targeting orthopedic applications plays a vital role in the improvement of mechanical properties. Metal oxides (MO) such as Al_2O_3 (Wong *et al.*, 2005), TiO_2 (Meenashisundaram *et al.*, 2015b), Y_2O_3 (Tun and Gupta, 2007), ZrO_2 (Hassan *et al.*, 2013) and ZnO (Tun *et al.*, 2013) have been successfully used as a secondary reinforcement in the Mg matrix owing to their enhanced mechanical and thermal behavior at elevated temperatures. The MO NPs do not undergo further oxidation and are chemically presenting an exciting alternative in the composite technology, not only in the ease of handling and processing but also in improving the properties of the metal matrix. Further, calcium phosphate-based reinforcements have also been viable to improve the overall properties of magnesium (Parande *et al.*, 2018a; Kuśnierczyk and Basista, 2017; Ratna Sunil *et al.*, 2014; He *et al.*, 2011). Some of the interesting results are discussed in this section and presented in Table 3.

Recent developments in magnesium matrix composites

Zhang *et al.* (2014) studied the microstructure and mechanical response of Alumina (Al_2O_3) fibers and particles containing AM60-based hybrid composite. The microstructure studies revealed that both the fibers and particles were uniformly dispersed within the magnesium alloy matrix with limited agglomeration. The elastic modulus, hardness, tensile strengths of the hybrid composites were observed to be higher than that of the AM60 matrix alloy.

In a study, Mg-2 vol% SiO_2 composites displayed excellent refinement in grains with superior mechanical and damping properties (Parande *et al.*, 2016). From the corrosion perspective, the addition of bioglass also improved the mechanical response and biocompatibility and reduced the hydrogen evolution in the composites (Radha and Sreekanth, 2017). These properties of the composites were found to be comparable to the natural bone making them an exciting choice for implant applications (Parande *et al.*, 2016).

Meenashisundaram *et al.* (2015a) used disintegrated melt deposition technique followed by hot extrusion to fabricate Mg- TiO_2 nanocomposites. Mg-1.98 vol% TiO_2 nanocomposite displayed the least grain size. Mg-2.5 vol% TiO_2 nanocomposite displayed an increment in yield strength, ultimate strength, and fracture strain of $\sim 37\%$, $\sim 9\%$, and $\sim 31\%$, respectively in comparison with monolithic magnesium.

Kujur *et al.* (2017) studied the influence of the addition of 0.5, 1.0, and 1.5 vol% of Sm_2O_3 NPs to the microstructural and compression properties of pure Mg. The grain size reduced with the progressive incorporation of Sm_2O_3 NPs to monolithic Mg.

Table 3 Mechanical and corrosion properties of magnesium-matrix composites

Mg-1.5 vol% Sm₂O₃ displayed the highest reduction of 46.7% in grain size as compared to pure Mg. NPs are fairly distributed in the magnesium matrix as shown in Fig. 10. Near uniform dispersion of secondary particles in the magnesium matrix is important for realizing Orowan strengthening leading to enhanced strength properties (Parande *et al.*, 2018b; Malaki *et al.*, 2019; Parande *et al.*, 2020; Gupta and Wong, 2015; Kumar Meenashisundaram *et al.*, 2017). Mg-1.5 vol% Sm₂O₃ nanocomposite showed the highest increase in the yield strength and ultimate strength of ~56% and 53% as compared to monolithic Mg. The fracture strain of Mg-Sm₂O₃ nanocomposites was similar to or higher than pure Mg.

Gu *et al.* (2010) used powder metallurgy process to develop Mg/(10, 20, and 30 wt%) HAP composite and studied the effect of HAP on the microstructure, corrosion, cytotoxicity, and mechanical properties. HAP particulates were observed to be agglomerated in the Mg matrix at regular intervals for the Mg/20 wt% HAP composite. The overall properties were observed to reduce with the presence of HAP for all the composites.

Chen *et al.* (2016) studied the strength properties of the AZ91, porous HAP, and AZ91/HAP composite. It was observed that AZ91 displays higher strength and fracture strain values as compared with the HAP and HAP containing AZ91 composite. Although, porous HAP displays lower strength and ductility values as compared to AZ91 and HAP containing AZ91 composite. The presence of HAP particles greater than 10 wt% resulted in the decrement of yield strength and ultimate strength, under tensile mode. This was owing to the high amount of clustering of HAP particles resulting in the formation of defects and pores at the matrix level (Hassan and Gupta, 2005).

Khanra *et al.* (2010) compared the effect of chemically sterilized HAP powder (0, 5, 10, and 15 wt%) HAP on Mg and ZM61 alloy synthesized using the extrusion process. The grain size with the presence of HAP decreased for both Mg and ZM61 alloy. The tensile strength of the composites decreased with the progressive addition of HAP. Further, the compressive strength of the composites increased and the ductility of the composites decreased with the presence of HAP. Xu *et al.* (2009) studied that the Mg–15% HAP composites displayed superior yield and ultimate strengths in compressive modes but a decreased tensile strength properties due to the increased addition of HAP.

Parande *et al.* (2018a) studied the effect of the addition of (0.5, 1, and 1.5) vol% β -tricalcium phosphate (β -TCP) on the microstructure, damping, and immersion characteristics of monolithic Mg. The presence of β -TCP improved the yield strength, ultimate strength, and fracture strain under compressive mode by about ~34%, ~53%, and ~22%, respectively, in comparison

Fig. 10 Scanning electron microscopy (SEM) images showing the distribution of Sm_2O_3 nanoparticles (indicated by the arrows) in Mg- Sm_2O_3 nanocomposites: (a) Mg-0.5 vol% Sm_2O_3 (b) Mg-1 vol% Sm_2O_3 (c) Mg-1.5 vol% Sm_2O_3 (d) interfacial integrity of Mg-1.0 vol% Sm_2O_3 nanocomposite. Reproduced from Kujur, M.S., Mallick, A., Manakari, V., *et al.*, 2017. Significantly Enhancing the Ignition/Compression/Damping Response of Monolithic Magnesium by Addition of Sm2O3 Nanoparticles. *Metals* 7 (9), 357.

with pure Mg. Mg-1.5 vol% β -TCP composite showed a superior $\sim 70\%$ grain refinement when compared to pure Mg (Fig. 11). Refined grain size is vital in improving the yield strength of magnesium composites by activating Hall-Petch strengthening (Parande *et al.*, 2020; Yan *et al.*, 2017; Parande *et al.*, 2018c).

Parande *et al.* (2019) reinforced low cost (3, 5, and 7 wt%) eggshell (ES) particles to develop Mg-2.5 wt% Zn composites synthesized using an energy-efficient DMD process. The presence of 3, 5, and 7 wt% ES displayed a compressive yield strength (0.2CYS) to be ~ 113 MPa, ~ 116 MPa, and ~ 117 MPa, respectively, which is $\sim 3.6\%$, $\sim 6.4\%$, and $\sim 7.3\%$ as compared to that of the Mg-2.5Zn alloy (~ 109 MPa). Mg-2.5Zn-3ES and Mg-2.5Zn-5ES composites showed a fracture strain value of $\sim 30\%$ and $\sim 34\%$, respectively. This is a $\sim 14.5\%$ and $\sim 29.7\%$, respectively enhancement compared to the Mg-2.5Zn alloy.

Mg-40 vol% bredigite composites synthesized using the powder metallurgy process displayed strength properties similar to that of natural bone. The degradation of Mg was decreased 24 times with the presence of bredigite particles in the Mg matrix (Dezfuli *et al.*, 2017). Mg60Zn35Ca5BMGC containing 40 vol% of Ti particles displayed a near-uniform lower rate of degradation when compared to other composite formulations. Mg60Zn35Ca5BMGC experiences slower anodic dissolution of Mg^{2+} and hence the corrosion protection is observed to better with the presence of the reinforcement (Wong *et al.*, 2017).

Mg-matrix bio-nano composite containing HAP, MgTiO_3 , $\text{Mg}_3(\text{PO}_4)_2$, and $\text{Mg}(\text{OH})_2$ phases was studied (Khalajabadi *et al.*, 2015). It was observed that the increased milling times and HAP amounts resulted in a lower corrosion rate in the SBF solution revealed.

The effect of reinforcing various amounts of Fluorapatite (FA) nanoparticles (10, 20, 30 wt%) on corrosion and mechanical response of AZ91 alloy was studied (Razavi *et al.*, 2010). The corrosion properties were improved with the presence of FA and a progressive increase in FA improved the corrosion resistance further. Formation of a protective hydroxide layer on the surface of the composite thereby facilitating surface protection and potential for bone remodeling (Yan *et al.*, 2017). A reduction in the deformability of the AZ91 alloy was observed with the increased presence of FA reinforcements. The presence of hard FA ceramics was observed to increase the hardness behavior of AZ91 alloy. This was owing to the presence of FA particles at the matrix interface thereby obstructing the deformation locally during the indentation. The improvement in corrosion resistance was observed with the increase in the amount of FA in AZ91 alloy (Razavi *et al.*, 2010).

In a study, Cao *et al.* (2017) used spark plasma sintering to synthesize in-situ Mg composites from Mg and ZnO powder. The corrosion properties were evaluated using immersion and electrochemical tests in the HBSS solution. Mg/10 wt% ZnO composite revealed an improvement in the corrosion resistance compared with the other formulations. Fig. 12 revealed the SEM of post

Fig. 11 Optical micrography images of Mg- β -TCP composites: (a) Mg-0.5 TCP; (b) Mg-1.0 TCP; and, (c) Mg-1.5 TCP. Reproduced from Parande, G., Manakari, V., Gupta, H., Gupta, M., 2018a. Magnesium- β -tricalcium phosphate composites as a potential orthopedic implant: A mechanical/damping/immersion perspective. *Metals* 8 (5), 343.

immersed Mg-ZnO samples. The observations revealed the calcium phosphate layer formation on the surface of the sample. This formation of the protective phosphate layer is known to have a pronounced effect on the osseointegration of the materials and hence can be a promising candidate for implant applications.

Shuai *et al.* (2020) studied the effect of MgO-coated reduced graphene oxide (RGO) containing AZ61 alloy synthesized using selective laser melting (SLM) process. The presence of MgO coated RGO improved the mechanical and corrosion behavior of AZ61 alloy when compared to only RGO addition to AZ61 alloy. Also, the progressive addition of the RGO/MgO content refined the grain size significantly. The grain size refinement due to the presence of reinforcement resulting in an improved hardness value from 90 ± 2 – 115 ± 2 HV with the progressive addition from 0 wt% to 4 wt%. AZ61-3 wt% RGO/MgO revealed the highest compressive strength of 221 ± 2 MPa which was 30% higher than the base matrix. This was attributed to the superior interfacial integrity between the magnesium matrix and the RGO/MgO reinforcement. The corrosion behavior of AZ61-3 wt% RGO/MgO composite exhibited the lowest corrosion rate of 1.05 mm/y.

Shahin *et al.* (2020) studied the effect of GNP on the microstructural and mechanical behavior of sintered Mg-Zr alloy. A near homogenous distribution of GNP was observed in the Mg-Zr alloy which was attributed to the optimized parameters used during high energy ball milling. The ultimate compressive strength was increased by $\sim 91\%$ with respect to pure Mg owing to the solid solution strengthening effect between the Mg, Zr, and GNP phases. The corrosion rate was decreased with the presence of GNP from 5.5 to 3 mm/y owing to the near-uniform presence of GNP and the refinement in grain size.

Saberi *et al.* (2020) studied the effect of xGNP ($x = 0, 0.5, 1.0$, and 2.0 wt%) graphene nanoparticles on the mechanical, corrosion and biological responses of Mg-3 wt% Zn-1 wt% Ca alloy synthesized using the semi-powder metallurgy process. The study revealed that 1 wt% of GNP addition observably enhanced the compressive strength. This was attributed to the refinement in grain size and superior interfacial integrity between the alloy matrix and the GNP reinforcement. However, the presence of 2 wt% GNP in the Mg matrix exhibited limited clustering in the matrix and reduced the interfacial bonding leading to a reduction in the strength properties. Electrochemical corrosion tests were performed and the Mg-3Zn-1Ca/1 wt% GNP composite showed the lowest corrosion current density ($112.89 \mu\text{A}/\text{cm}^2$). This was attributed to the pore filling on the surface of the composite. However, Mg-3Zn-1Ca/2 wt% GNP displayed a high corrosion current density ($420.76 \mu\text{A}/\text{cm}^2$) as compared to 1 wt%. Microgalvanic corrosion between Mg and GNP was attributed to this increase in corrosion density owing to the presence of matrix voids and cracks.

Parande *et al.* (2018a) studied the immersion response of Mg-TCP composites in HBSS. The presence of TCP significantly decreased the corrosion rate. All the TCP composites also displayed a near-uniform corrosion rate with the increase in immersion

Fig. 12 SEM observation of immersed Mg-ZnO samples in HBSS. Reproduced from Cao, N.Q., Pham, D.N., Kai, N., *et al.*, 2017. In vitro corrosion properties of Mg matrix in situ composites fabricated by spark plasma sintering. *Metals* 7 (9), 358.

Fig. 13 Optical micrographs of pure magnesium and Mg (0.5, 1.0, and 1.5) vol% β -TCP composites after 24, 48, 72, and 96 h of immersion. Reproduced from Parande, G., Manakari, V., Gupta, H., Gupta, M., 2018a. Magnesium- β -tricalcium phosphate composites as a potential orthopedic implant: A mechanical/damping/immersion perspective. *Metals* 8 (5), 343.

time. **Fig. 13** shows the optical micrographs of the samples under immersion. The pit formation post corrosion was evident in pure Mg and the TCP composites showed a lower prevalence of corroded pits. The SEM analysis of the corroded surface of the Mg-1.0 TCP composite samples post 96 h of immersion is shown in **Fig. 14** leading to severe cracking on the sample surface with two types of layers namely quasi-adherent layer and cracked layer being formed. Several uneven pits post corrosion with uneven sizes and microcracks were observed throughout the monolithic and composite samples.

Summary

The article discusses the recent trends in the field of eco-friendly metal matrix composites and briefly summarises the processing technologies and properties of the composites. The following observations have been drawn from this attempt.

- The metal matrix composite community has made significant strides in utilizing low cost inexpensive secondary reinforcements to replace high-density toxic metals to develop materials with holistic importance.
- In the case of zinc-based composites, several articles have been published on the influence of secondary reinforcements in various morphologies on the response of ZA27 alloy synthesized using various methodologies. Natural fillers, industrial wastes amongst others have been successfully used to develop high-performance zinc matrix composites. Going forward, it would be

Fig. 14 Scanning Electron Microscope (SEM) analysis of Mg-1.0 TCP composite post 96 h of Hanks balanced salt solution (HBSS) immersion. Reproduced from Parande, G., Manakari, V., Gupta, H., Gupta, M., 2018a. advisable to explore different options to alloy zinc to decrease the amount of aluminum in the alloy in the overall interest of recyclability and non-toxicity.

- In the case of titanium-based composites, additive manufacturing technologies have been used to a successful extent in the past decade. Using these processes to form near net-shaped products for aerospace industries and custom products for orthopedic implant sectors can gain higher acceptance. The influence of natural fillers like rice husk, eggshell, and industrial wastes like fly ash can be further explored. Replacing aluminum and rare earth elements with Nb, Zr, Si, Zn amongst others can be explored to improve the functional properties of the titanium matrix.
- In the case of magnesium matrix composites, the concept of Eco-Mg-based alloys has made a significant contribution to the knowledge of the design and development of low-cost high-performance magnesium materials. This approach can yield favorable results in weight critical applications in the transportation sectors and fracture fixation procedures in biomedical sectors. The possibility of producing these novel composites using additive manufacturing techniques can be explored in the future.

Introduction

Metal matrix composites (MMCs) are the materials which offer high strength to weight ratio, high stiffness, conductivity, fracture toughness (Mavhungu *et al.*, 2017; Ramanathan *et al.*, 2019; Miracle, 2005). It has the ability to withstand the elevated temperature even in corrosive atmosphere making them an attractive selection in replacing conventional materials for several engineering applications (Schmidt *et al.*, 2004; Suresh *et al.*, 2012; Singh *et al.*, 2020). Normally the metal matrix materials of MMCs are aluminum alloys, titanium alloys, copper alloys and magnesium alloys, while the reinforcement materials are silicon carbide, aluminum oxide, boron carbide, graphite etc. in the form of fibers, whiskers and particles. Perhaps the single most important difference between fiber reinforced and particulate composites or conventional metallic materials is the directionality of properties. Particulate composites and conventional metallic materials are isotropic, while the fiber reinforced composites are generally anisotropic. Particulate reinforced composites offer higher ductility and their isotropic nature as compared to fiber reinforced composites makes them an attractive alternative. The metal matrix composites have various advantages over other types of composites. Such as high strength, high modulus, high toughness and impact properties, Low sensitivity to changes in temperature or thermal shock, high surface durability and low sensitivity to surface flaws, high electrical conductivity. The inclusion of high strength and modulus ceramic reinforcements to a ductile metal matrix forms the metallic composites having unique combination of properties offering high resilience, high-temperature applications compared to polymer and ceramic matrix composites. From tribological perspective, the addition of hard ceramic reinforcements increases the wear resistance of the metallic matrix. Ultimate combination of properties of MMCs depends on a number of factors related to matrix, reinforcement, processing, and heat treatment (Singh *et al.*, 2020). The properties of MMC includes (1) high toughness and high impact properties (2) high thermal and electrical conductivities (3) excellent anti-abrasion, antifriction (4) excellent *machinability* (5) reduced wear (6) lightweight materials (7) good specific stiffness and strength (8) high in strength and (9) low ~~in~~ density.

Constituents and Classification of MMCs

Metal matrix composites can be classified in various ways. We may classify composites on the basis of the type of matrix employed in them for example, polymer matrix composites (PMCs), metal matrix composites (MMCs), and ceramic matrix composites (CMCs). We may also classify composites on the basis of the type of reinforcement they employ (Meyers and Chawla, 2008; Clyne and Withers, 1995). They are (1) Particle reinforced composites (2) Short fiber, or whisker reinforced, composites. (3) Continuous fiber, or sheet reinforced, MMCs and (4) Laminate composite (see Fig. 1).

Processing Methods of MMC

Metal matrix composite materials can be produced by many different techniques. The focus of the selection of suitable process engineering is the desired kind, quantity and distribution of the reinforcement components (particles and fibers), the matrix alloy and the application. By altering the manufacturing method, the processing and the finishing, as well as by the form of the reinforcement components it is possible to obtain different characteristic profiles, although the same composition and amounts of the components are involved. The production of a suitable precursor material, the processing to a construction unit or a semi-finished material (profile) and the finishing treatment must be separated. For cost effective reasons prototypes, with dimensions close to the final product, and reforming procedures are used, which can minimize the mechanical finishing of the construction units.

Development of fabrication processes for the production of high-performance composites has been reported in many research studies. The methods which are commonly used for fabrication of the MMCs are (1) Solid-phase processing and (2) Liquid-phase processing (Bains *et al.*, 2016).

Fig. 1 Schematic presentation of (a) particle reinforcement; (b) short fiber reinforcement; (c) continuous fiber reinforcement; (d) laminate reinforcement.

The adoption of the route for the synthesis of MMCs depended on many factors including the matrix temperature during processing, extent and reinforcement loading, and desired degree of microstructural integrity. Well-established methods in solid-state processes include blending of powder followed by isostatic pressing (powder metallurgy (PM) processing), spray deposition techniques, and diffusion bonding. Melt stir casting, melt infiltration, spray casting, and in situ (reactive) processing come from liquid-state processing (Bains *et al.*, 2016). Other techniques include in situ processes and two phase (solid-liquid) processes.

Liquid State Fabrication of Metal Matrix Composites

The molten matrix and reinforcements are *unified* together by solidification mechanism (Sahu and Banchhor, 2016). In the liquid state casting technique, the particulates are mechanically well distributed over the liquid metal before casting and solidification (Estrada-Guel *et al.*, 2009). These methods are typically cost effective (Kerti and Toptan, 2008). The following are the various processing methods which come under liquid state fabrication techniques.

Stir Casting Process

Stir casting is the most economical and commercially adopted technique for the production of metal matrix composites. It is also known as “vortex technique” (Attar *et al.*, 2015). In this technique, reinforcing phases (ceramic particles, short fibers/whiskers) are introduced in to the molten metal by means of mechanical stirring (Fig. 2). In 1968 Ray initiated the stir casting of particulate aluminum metal matrix composite by introducing alumina (Al_2O_3) particles in to molten aluminum alloy by mechanical stirring (Giot *et al.*, 1987). The agglomeration of particles during fabrication is the major drawback of stir casting process (Nienow *et al.*, 1997). If the dispersion of reinforcement particles is not uniform, then they have high tendency to agglomeration and clustering. If the reinforcement particles are *not stirred properly* in molten matrix, they *will* tend to sink or float to the molten melt due to the density differences between the reinforcement particles and the matrix alloy melt. By injecting the reinforcement particles with the aid of an inert gas supply into the melt helps in improving the distribution of the particles (Hashim *et al.*, 1999).

Many research studies suggested that reinforcement in particulate form up to 30% by weight can be added in molten alloy, to achieve better distribution of the reinforcement (Luo, 1995). Reinforcement particles are added in to the molten aluminum alloy and the homogeneity of the added particulates during solidification of composite depends on following factors; (a) Stirring speed and time (b) Stirring blade angle (c) Pouring temperature and solidification rate (d) Reinforcement’s size, percentage and its relative density.

Compocasting Process

In recent years, researchers have identified compocasting as one of the economic and efficient methods for fabricating aluminum matrix composites (AMC) over other conventional methods due to its advantages like low casting temperature, uniform distribution of reinforcement without agglomeration, good wettability and better matrix-reinforcement bonding (Rosso, 2006). Compocasting is a solid-liquid state method in which a vortex is created in the semisolid molten metal (between the solidus and liquidus temperature of the matrix alloy) using an impeller driven by an electric motor, and the reinforcements are added into the vortex under stirring. During compocasting process, the higher viscosity of semisolid molten metal slurry transmits shear force over the agglomerated reinforcements which lead to better dispersion and distribution of reinforcement in the matrix. Both the micron and nano size reinforcements are successfully incorporated into the matrix by compocasting process.

Fig. 2 Schematic diagram of stir casting process.

The major process parameters considered during compocasting process are (1) crucible size (2) size and shape of the stirrer (3) semisolid metal temperature (4) stirring time (5) stirring speed (6) mold temperature and (7) reinforcement feeding rate. The properties of the final composite depend on the aforesaid process parameters (Kok, 2005). The compocasting process has two variations namely semisolid–semisolid (SS) and semisolid–liquid (SL) routes, in which the matrix alloy during casting step is either in partially liquid or in fully liquid state respectively. However, during compocasting process the matrix will be in the semi-solid state for both the variations and the reinforcements are added into it. Both the variations have its advantages and disadvantages, some of the benefits of SS route are (1) low processing temperature (2) lower interfacial reaction (3) low solidification shrinkage, etc. While considering the benefits of SL route they are (1) ease of casting, (2) less porosity etc. (Akhlaghi *et al.*, 2004).

Spray Deposition

Fabrication of composite by spray forming process involves melting of an alloy in a furnace, forcing the melt through a small orifice, passing a stream of compressed inert gas, injecting reinforcement through the jet and breaking the liquid metal into fine semi solid droplets. These semi solid droplets are deposited over a stationary substrate to form solid preform (Fig. 3). It is difficult to attain uniform distribution of reinforcements into the metal matrix by this method but the composites formed by spray deposition process are not very expensive (White *et al.*, 1987).

Disintegrated Melt Deposition Technique (DMD Technique)

DMD technique is a liquid-state processing method, which is more suitable for the fabrication of nano composites. This technique has the combined advantages of gravity die casting and spray deposition technique (Gupta and Sharon, 2011). The DMD process offers higher superheat temperatures and lower impinging gas jet velocity which attribute to uniform distribution of nano sized reinforcement particles with the absence of agglomeration, minimum interaction time of nanoparticles with matrix in the molten state, elimination of impurities/oxides (Ceschini *et al.*, 2016). This process involves addition of nano ceramic particles by mechanical stirring into the molten metal/alloy with an impeller. The composite slurry thus formed is then allow to exit from the bottom of the crucible through a nozzle, followed by disintegration of melt by jets of inert gas at a superheat temperature of 750°C and is finally deposited onto a metallic substrate (Fig. 4). The disintegration of composite melt ensures higher solidification rate and fine-grained structure. This processing technique can be employed for the fabrication of aluminum and magnesium nano composites (Jayalakshmi *et al.*, 2016).

The main challenges of this process are (1) Not suitable to produce cast components as the method is suitable to produce Metal Matrix Nano Composite ingots to be used as precursors for making wrought products, (2) difficult to be automated and to be used for continuous casting operations unless modifications are made in equipment design.

In-Situ Processing

In-situ synthesis is a process wherein the reinforcements are formed in the matrix by controlled metallurgical reactions with various reinforcement ceramic particles such as SiC, AlN and TiC (Zawrah and Aly, 2006; Daoush *et al.*, 2015; Nie *et al.*, 2014). In

Fig. 3 Schematic diagram of spray forming process.

Fig. 4 Schematic diagram of DMD process.

this process, a reinforcement phase is introduced in the matrix phase as an outcome of precipitation from the melt while it cools and solidifies. During fabrication, one of the reacting elements is usually a constituent of the molten matrix alloy. The other reacting elements may be either externally-added fine powders or gaseous phases, final reaction products is the reinforcement dispersed in matrix alloy (**Fig. 5**). It is difficult to disperse the reinforcing particles uniformly in metal melts due to the low wettability with the melt (**Jamaati and Toroghinejad, 2010**). The main difficulty in the process is the reaction of particle size of less than 1 mm, particle agglomeration and serious health hazards (**Changizi, 2005**). The interface bonding may be lowered due to the porosity and segregation at the interface between the matrix and reinforcement (**Aghajanian et al., 1991**). It requires the higher reaction time temperature and longer holding time *which greatly increases the cost of production*.

Fig. 5 Schematic diagram of in situ direct reaction synthesis apparatus.

Fig. 6 Schematic diagram of the electromagnetic melt stirring apparatus with ultrasonic vibration.

Ultrasonic Processing

There are mainly two types of ultrasonic processing system have been used for the manufacturing of metal matrix composites, these are contact (Yang *et al.*, 2004; Yang *et al.*, 2004) and noncontact-type (Padhi and Kar, 2011). In case of contact-type, the ultrasonic probe is dipped into the liquid melt that directly aids to disperse the micro or nano reinforcement particles in the melt and the developed slurry is subsequently solidified by conventional casting route. Whereas in noncontact-type, solidification of liquid melt with added nanoparticles is performed in an ultrasonic chamber (Padhi and Kar, 2011). The contact-type system is the most preferred system by considering its simplicity in operation and effectiveness to disperse nano/micro particles in melt. A typical contact-type Ultrasonic processing apparatus is schematically illustrated in Fig. 6.

The ultrasonic processing involves mainly two important phenomena, i.e., transient cavitation and acoustic streaming (Yang *et al.*, 2004; Li *et al.*, 2004). The acoustic cavitation is initiated by the high-intensity ultrasonic waves (above 25 W/cm^2) that generate strong non-linear effects in the molten metal (Yang *et al.*, 2004; Yang *et al.*, 2004; Borgonovo and Apelian, 2011). The effect of such cavitation includes the formation, growth, pulsating, and collapsing of micro air bubbles that tend to be trapped inside nanoparticle clusters during the negative and positive pressure cycles (Choi *et al.*, 2012). The strong cavitation can create transient (in the order of nanoseconds) micro "hot spots" that generate temperature of about 5000°C , pressure of above 1000 atms, and heating and cooling rates above 1010 K/s (Cao *et al.*, 2008; Li *et al.*, 2007). The severe implosive impact in conjunction with local transient high temperature can effectively fracture nano/micro particle clusters, clean the particle surface and enhance the wettability between melts

Fig. 7 Classification of infiltration process for the fabrication of metal matrix composites.

and particulates (Yang *et al.*, 2004; Li *et al.*, 2004). Acoustic streaming flows throughout the melt and helps to circulate nano/micro particles all over the melt. Compared to conventional castings, Ultrasonic processing technique proves to be more reliable for producing nanocomposites even with system having extreme difference in thermal coefficients between metal matrix and ceramic particulates (Li *et al.*, 2007).

Liquid Metal Infiltration

Liquid metal infiltration of ceramic preform is one of the best suited processing technique to produce metal matrix composite components with high volume fraction of reinforcement. Through this method it is possible to fabricate *composites* with variety of complex shapes. Infiltration is a liquid-state fabrication method, in which a porous preform (reinforcement) made of ceramic particles, fibers, woven etc. are impregnated in a molten matrix metal, which fills the pores between the dispersed-phase inclusions. Synthesis of porous ceramic preform with sufficient mechanical strength, uniform pore distribution, pore size, and porosity level is one of the crucial steps involved in the infiltration processing of composites (Manu *et al.*, 2016). Some of the important fabrication methods for porous ceramic foams are polymer replica techniques, gel casting, direct foaming of suspensions, and using pore-forming agents (PFA) (Colombo and Hellmann, 2002; Sepulveda, 1997; Montanaro *et al.*, 1998). Al, Mg, and Cu based alloys have been successfully used as matrices to fabricate MMCs through liquid infiltration, as they can be easily melted and handled in the liquid state. Difference from one infiltration method to another is based on the technique that is used to drive the molten metal to enter the preform.

The liquid infiltration processes can be broadly classified into two categories: (1) spontaneous infiltration and (2) forced infiltration (Fig. 7). When capillary action of the reinforcement phase acts as a driving force for infiltration, the category of processes is termed as spontaneous infiltration. In forced infiltration an external pressure such as gaseous, mechanical, squeeze, electromagnetic etc. are applied to the liquid matrix phase which accelerates the infiltration of molten metal through the preforms. The processing details are explained here.

Spontaneous/pressure-less infiltration

In spontaneous infiltration, the molten liquid metal invades into the voids of the porous body without the application of any external forces (Fig. 8). This can be accomplished with the help of controlled temperature and gas atmosphere ensuring good wetting conditions are maintained for self-permeation (Lee *et al.*, 2009).

Forced Infiltration

The infiltration process in which the aid of an external pressure or mechanical force governs the infiltration of liquid metal into the porous reinforcement is called forced infiltration. Poor wetting between the molten metal and porous structure can be overcome by endowing mechanical energy to force the metal into the porous preform. There are various types of forced infiltration methods and these are described below.

Gas pressure infiltration

An infiltration process in which pressurized gas (Fig. 9) is used as driving force for the penetration of molten metal into the porous body. Gas infiltration process is normally carried out in combination with vacuum at the other end of the preform to get rid of entrapped air to facilitate easy penetration at lower gas pressures (Carreno-Morelli *et al.*, 1998). As a result, high pressure is needed for complete infiltration of molten metal, hence, anti-pressure of gases is to be considered during the analysis of threshold pressure. With the ideal gas equation $PV = nRT$, the anti-pressure of gas can be expressed as (Qi *et al.*, 2012)

$$p_g(z) = \frac{p_0 T_z L}{T_0 [L - Z]}$$

where p_0 is the pressure of gas at initial time, T_0 is the initial time temperature, L is the preform total length, and T_z is the

Fig. 8 Schematic diagrams showing the working principle of spontaneous infiltration process: (a) infiltration takes place at controlled atmosphere, (b) progressiveness of infiltration, and (c) final composite.

Fig. 9 Schematic illustrations of gas pressure infiltration process for the fabrication of MMCs: (a) infiltration process carried out with vacuum to remove the entrapped air in the preform to facilitate easy molten metal penetration, (b) applying pressurized gas as a driving force for metal infiltration, and (c) final composite.

temperature of the gas when the infiltration attains a height z . Enhance in the infiltration temperature and pressure during gas pressure infiltration process improves the relative density of the component, which shows an effect on the mechanical properties of the final composite (Manu *et al.*, 2016).

Pressure die infiltration

Pressure die infiltration process involves placing a porous preform inside a solid die and applying pressure with the help of a movable piston to allow penetration of liquid metal in the porous preform (Fig. 10 (a) and (b)). Process parameters that are optimized include speed, die temperature, and pressure of the piston. Main advantages of this process are low cost and ability to fabricate components of high complexity and precision. The deformation of preform due to the pressure of the molten metal

Fig. 10 Schematic diagrams of pressure die infiltration process for the fabrication of MMCs: (a) before applying pressure to molten metal using plunger and (b) after applying pressure to molten metal using plunger to form the composite.

Fig. 11 Schematic of a conventional centrifugal infiltration process.

before and during infiltration will be high for pressure die casting compared to squeeze casting owing to high compression rate of preform during infiltration.

Centrifugal infiltration

In centrifugal infiltration process, rotational/centrifugal force is used to infiltrate porous preform with liquid molten metal. During the fabrication of composites, porous reinforcement material is positioned inside a mold (at the end) having an elongated runner, which was filled with molten metal. Large rotational velocities of the runner initiate centrifugal force with required drive for infiltration to overcome the threshold pressure for melt penetration and viscous forces of the molten metal to flow in the preform. (Fig. 11). The molten metal pressure exerted on the porous preform during centrifugal force is given by (Wannasin and Flemings, 2005)

$$P_c = \frac{1}{2} \rho \omega^2 (L_2^2 - L_1^2)$$

where ρ is the density of molten metal, $\omega = \frac{2\pi N}{60}$, N is the rotational speed in rpm, and L_2 and L_1 are the outer and the inner molten metal's level from the rotation axis.

Lorentz force infiltration

Lorentz force infiltration process is a novel infiltration process in which electromagnetic force is used to propel the molten metal into the ceramic preforms. During the process, the preform gets immersed in a liquid molten metal which is subjected to a high-frequency magnetic pulse. Simultaneously, eddy current persuaded in the liquid metal gets to interact with the magnetic pulse and develop a Lorentz body force in the liquid molten metal causing the liquid metal to enter into the ceramic preform at a high speed.

Fig. 12 Schematic diagram of the ultrasonic vibration apparatus.

Fig. 13 Schematic diagram showing the working principle of vacuum infiltration process for the fabrication of MMCs.

Andrews and Mortensen had successfully fabricated void-free aluminum/ Al_2O_3 fiber composite by Lorentz force infiltration technique. They suggested that the infiltration depth depends on the nature and number of discharges (Mortensen and Jin, 1992).

Ultrasonic infiltration

In ultrasonic infiltration process, pressure waves generated by the ultrasonic vibration assist in the penetration of the molten matrix material in the ceramic preform. When ultrasonic vibration is actuated through a horn in the liquid molten metal, acoustic cavitations (bubbles) are originated. The air entrapped in the porous preform and the dissolved gas in the molten metal can become the cavitations' nuclei. When a bubble collapses shock wave originates close to the molten metal resulting in infiltration process (Fig. 12) (Pan *et al.*, 1995; Deming *et al.*, 1993). The important process parameters considered for the ultrasonic infiltration is ultrasonic power, hole in the horn, and fabrication speed. Increase in the diameter of the hole in the horn decreases the infiltration ratio due to the depletion in the formation of acoustic cavitations and studies show that optimum diameter of the hole is 5 mm. The system which undergoes ultrasonic vibration shows reduction in contact angle due to heavy vibration acceleration and thereby improving wettability (Sasaki *et al.*, 2005).

Vacuum infiltration

Vacuum infiltration involves a negative pressure infiltration in which matrix metal gets penetrated into the evacuated preform due to the application of suction pressure (Fig. 13). Process parameters like infiltration temperature, infiltration time, and applied vacuum ($\sim 300\text{--}500$ mmHg) play a crucial role in this process (Gul and Acilar, 2004). Infiltration rate gets increased with increasing the molten metal temperature and by applying coating on the reinforcement, thereby reducing the infiltration incubation period to avoid brittle interfacial reactions (Chung *et al.*, 1999). Low solidification rate of the final component during processing can be stepped up as one of the disadvantage of vacuum infiltration which enhances the grain growth of the matrix metal and interfacial reaction between matrix and the reinforcement (Yang and Chung, 1989). To avoid the liquid molten metal

Fig. 14 Schematic diagrams of squeeze infiltration process for the fabrication of MMCs: (a) before the application of squeeze pressure and (b) after the application of squeeze pressure as a driving force to infiltrate molten metal into the preform.

getting into the vacuum pump by chance during infiltration process one portion of the connection pipe is filled with metal chips, so that the molten metal entering into the pipe gets solidified in that particular area without damaging the vacuum pump. Studies have shown that Al and Mg based composite materials with more than 50 vol pct reinforcement can be successfully fabricated using vacuum infiltration technique (Xiong *et al.*, 2011).

Squeeze infiltration

Squeeze infiltration is one of the widely used method for the production of near net shape metal matrix composites with close control over shape, volume fraction, chemistry, and distribution of reinforcement (Beffort *et al.*, 2007; Rohatgi *et al.*, 2006; Deqing *et al.*, 2001). This process offers advantages over other conventional methods for fabricating composite components which are difficult to be machined. The process involves the formation of porous preform as the reinforcement and its infiltration with the molten matrix material under pressure (Fig. 14) typically in the range of 50–100 MPa (Mortensen, 2000). The appropriate magnitude of applied pressure ensures eradication of porosities, refined microstructure, enhanced processing speed, and termination of chemical reactions. For the development of quality composites processing parameters of squeeze infiltration have to be optimized.

Applications

The automotive market represents the largest current market for Aluminum MMCs on a volume basis. The potential for AlMMCs in this area is barely tapped, however, and represents a great opportunity for substantial growth. Through R&D, lighter, engineered materials are being developed which offer better performance than the existing materials. Replacement of steel and cast iron in internal combustion engine applications as well as in unsprung weight components, such as the brake system, is judged the most promising for the near term. Aluminum metal matrix composites are suitable replacements, not only for steel but also for aluminum alloys in various automotive systems and components. Aluminum-based engine blocks, suspension components, body panels and frame members are increasingly becoming common (Lutsey, 2010). Aluminum alloys and composites are also competing to replace many various traditional steel components in vehicles, such as valve covers, torque converter and transmission housings, crankcase, control arms, cradles, suspension links, door frames, steering wheels, dashboards, sheet panels and beams are also being replaced by alloy aluminum alloys and composites (Caceres, 2007).

Aluminum alloys and composites have played a big role in the advancement of aircraft and rocket technology. Aluminum alloys and/or composites are the favored choice for the fuselage, wing and supporting structures of commercial airliners and military or cargo aircraft. Aluminum metal matrix composites have been the material of choice for space structures of all types ever since the launch of Sputnik 1 (October 4, 1957). Chosen for their light-weight and their ability to withstand the stresses that occur during launch and operation in space, AlMMCs and alloys have been used on Apollo spacecraft, the Skylab, the space shuttles and the International Space Station. Aluminum alloys/composites consistently exceed other metals in such areas as mechanical stability, dampening, thermal management and reduced weight (Finckenor, 2017).

The University of Wisconsin-Milwaukee (UWM) reportedly developed aluminum alloy pistons and cylinder liners containing dispersed graphite particles that provide solid lubrication (Macke *et al.*, 2012). The graphite-containing aluminum has a lower friction coefficient and wear rate and does not seize under boundary lubrication. Aluminum/graphite pistons and liners were

tested in gas and diesel engines and in race cars, and the results showed reduced friction coefficients and wear rates. The friction coefficient of Al-graphite composites was measured and found to be as low as 0.2 (Rohatgi *et al.*, 1992). This makes it a suitable material for cylinder liners in light-weight aluminum-engine blocks, for its ability to enable engines reach operating temperatures more quickly while providing superior wear resistance, improved cold start emissions and reduced weight (Gumus, 2009). Aluminum-based composite liners can be cast in situ using conventional methods, including sand, permanent mold, die casting and centrifugal casting.

Components such as control arms or wheel hubs made of strong silicon carbide (SiC)-reinforced aluminum or aluminum nanocomposites can further improve aluminum alloy designs by enhancing strength while using less material than similar aluminum arms (Withers and De Waas Tilakaratna, 2005).

Heat sinks play two key roles in electronic packaging: thermal management and mechanical support. Heat sinks support electronic devices and provide a path for heat dissipation. They are used in packages and with printed circuit boards (PCBs). Traditional heat sinks were primarily aluminum, copper or unalloyed blends of two metals, such as copper-tungsten or copper-molybdenum. The traditional heat sinks have exhibited a number of shortcomings, which has necessitated designing of new improved materials, primarily composites reinforced with fibers and particles. The new materials exhibit better properties including high thermal conductivities; low, controllable coefficients of thermal expansion; weight reductions; high strength and stiffness; and availability of net-shape fabrication processes. Utilization of composite materials is not a new phenomenon in electronic packaging. Aluminum metal matrix composites with the high volume fraction of reinforcement are attractive materials for thermal management. This is in view of the possibility to further enhance the thermal conductivity (TC) of the composite material by the use of high TC reinforcements and the flexibility to adjust the CTE by controlling the volume fraction of the reinforcement. Aluminum and copper were usually used as matrices due to their high TCs, and the reinforcements involved SiC, carbon and diamond. However, owing to the fact that the specific thermal conductivity of aluminum-based composites was higher than that of Cu-based composites, aluminum-based composites are more desirable in avionic applications where light-weight is demanded (Zweben, 2005).

Conclusion and Future Scope

MMCs are the material exhibiting properties that are hard to be obtained from monolithic material. The use of metal matrix composites is increasing day by day due to their characteristics of behavior with their high strength to weight ratio. These can be tailored and used as per the demands of various industrial applications by suitable fusion of their constituent materials. Every industry like automobile, sports, aerospace, thermal packaging, construction, marine, etc., utilizes the benefits of composites especially metal matrix composites. Various processes like stir casting, compo-casting, liquid metal infiltration etc., are used to manufacture MMCs as discussed in this article. Fabrication of MMCs determines the correlation between properties and cost of the material for a given set of constituents. Compatibility between matrix and reinforcement is a significant necessity for fabrication.

Each combination can be easily processed into useful composites. However, some research investigations suggest that tailoring the metal matrix interfaces is possible in order to cope with compatibility. Economical fabrication techniques, less costly materials, and judicious surface modification methods should be given attention as research and development priorities.

Introduction

MMCs exhibit superior mechanical properties, such as higher specific strength and specific elastic modulus than their monolithic counterparts when properly designed and processed (Mortensen and Llorca, 2010). During the past four decades, more and more cost-effective processing and characterization techniques have been developed leading to more frequent applications of MMCs in military, aerospace, electronics, ground transportation and some recreational and infrastructure industries (Miracle, 2005; Zhang *et al.*, 2020). The progressive increase in applications of MMCs has also triggered more research for further advancement in their overall development including processing techniques.

The key points for achieving good mechanical properties of MMCs are the combination of uniform dispersion of reinforcements, good interfacial bonding between metallic matrix and reinforcements, and good structural integrity of reinforcements. To obtain a good combination of these three factors, it is essential to choose an appropriate processing method. In general, according to the different routes of incorporating reinforcements into matrix, the processing methods can be categorized into four types, namely, liquid-state processing, solid-state processing, gaseous-state processing and two-phase processing.

Compared to liquid-state processing methods, the solid-state ones are easier to control to realize uniform reinforcement distribution and homogeneous matrix microstructure (Chawla and Chawla, 2013). In addition, the lower temperatures involved in solid processing can suppress the adverse interfacial reactions between the matrix and reinforcements, which is conducive to obtaining superior mechanical properties. Besides, solid-state processing methods have much lower requirements for equipment, when compared to gaseous-state processing methods, like physical vapor deposition (PVD). Therefore, solid-state processing methods are always important during the whole development process for MMCs, which have been attracting much attention.

The aim of this article is to provide an overview of the progress in solid-state processing methods, including the primary preparation techniques and secondary thermal mechanical processing methods. The novel processing routes developed recently are also described in detail.

Powder Metallurgy

The most common solid-phase processing methods of MMCs are based on powder metallurgy (PM). In fact, it can be employed to fabricate all types of discontinuously reinforced MMCs due to the ease of dispersing discontinuous reinforcements. According to the different methods of adding the reinforcements into the metallic matrix, PM routes can be divided into two types: (1) ex-situ processing route, and (2) in-situ processing route. The ex-situ route usually involves three steps: (1) directly mixing of metal and reinforcement powders to achieve uniform dispersion of reinforcements, (2) consolidation of composite powders, and (3) sintering. In most of these cases, the fully dense compacts are subjected to post-sintering deformation processes, such as hot extrusion, hot forging, hot rolling and severe plastic deformation, which will be described in Section "Thermo-Mechanical Processing (TMP)". For in-situ route, the essential difference is that the reinforcements are generated by in-situ reaction at the initial stage of the processing. All other steps are almost the same as the ex-situ one.

There are several advantages of PM over other preparation routes. The main advantage is that any designed composition of MMCs can be synthesized exactly, because PM is not dictated by thermodynamics and the phase diagram as in the case of liquid metallurgy (Agarwal *et al.*, 2011). In addition, there is little loss of the materials during PM and the final components with intricate shapes can be fabricated, almost with no need for further machining.

Forthcoming section will describe the main stages involved in conventional PM processing in detail, and introduce some new techniques based on PM, which are proposed recently.

Conventional Methods

Dispersion of reinforcements

The dispersion of reinforcements in the composite powders is crucial, which can almost determine the distribution of the reinforcements in the final MMCs, because the following processes, such as compaction and sintering, do not improve the dispersion further. To uniformly disperse the reinforcements in metal matrix, two different methods, namely blending and mechanical alloying, are usually employed. The former method normally involves dry mixing the metallic powders with the desired volume fraction of reinforcements. This method can be used to incorporate reinforcements such as ceramic particulates

Fig. 1 Schematic diagram showing (a) ball milling process, and (b) ball-powder-ball collision of powder mixture during mechanical alloying. Reproduced from (a) Gupta, M., Sharon, N.M.L., 2011. *Magnesium, Magnesium Alloys, and Magnesium Composites*, first ed. New Jersey: John Wiley & Sons. (b) Suryanarayana, C., 2004. *Mechanical Alloying and Milling*, first ed. New York: Marcel Dekker.

and short fibers, into the matrix but the uniformity remains limited (Ibrahim *et al.*, 1991). As for nano reinforcements, particularly, mechanical alloying involving high energy ball milling process is a much better choice. The composite powders undergo high-energy collision during ball-milling as shown in Fig. 1 which is beneficial to disperse the reinforcements and obtain refined grains in metallic matrix (Suryanarayana, 2004). The drawback of the methods is that the high-energy collision will destroy the structural integrity of the reinforcements, especially for the nano carbon materials with special structure, such as carbon nanotubes (CNTs) and graphene nanoplates (GNPs), which will reduce the strengthening effects of these nano reinforcements, resulting in dissatisfactory mechanical performance (Tjong, 2013). The improvement measures for solving this problem will be discussed in Section “Novel Methods”.

Compaction

The compaction stage is important for consolidation of the loose powder to obtain fully dense compacts. According to different pressing routes, commonly used consolidation processes can be categorized into two types: (1) uniaxial pressing, and (2) isostatic pressing.

For uniaxial pressing, the ball-milled or blended composite powders are poured into a metal die cavity, and then apply pressure directly in one single direction. Finally, the powder mixture is compacted into a solid piece and subsequently removed from the die.

For the latter pressing method, the essential difference from the former one is that the pressure is applied from all directions. In addition, the composite powders are filled in a flexible membrane or hermetic container, which creates a pressure barrier between the pressurizing medium and the powder mixture. The pressurizing medium used can be either gas or liquid. This method can achieve uniform compaction pressure throughout the compact, leading to a uniform density distribution in the end composite product. However, due to its higher cost and slower processing speed, it is only employed to prepare small quantities and simple shaped materials (Gupta and Sharon, 2011).

Hot pressing can be conducted for both of the two methods by applying pressure and heating simultaneously. Once hot compaction or hot isostatic pressing is utilized, the sintering step is often not required.

Sintering techniques

Sintering process determines the interface bonding between the powders and has a significant effect on the relative density of the final product. The heating temperature is always traditionally below the material's (metallic matrix) melting point. Fig. 2 shows the schematic diagram of different sintering stages. It can be seen that necks are formed along the powder contacts at the initial sintering stage, and the voids also are formed during this stage. As the sintering process progresses, the voids gradually diminish in size, resulting in a denser compact. However, it is hard to produce the compact without any void, thus, the relative density of the MMCs fabricated by PM is usually less than 100%.

For conventional method, the heat for sintering is generated by external sources such as a resistive heating element. The powder mixture is heated through conduction, convection, and radiation. The weak point of conventional sintering is that high temperature and long sintering time should be used to obtain dense products with good interfacial bonding (Tjong, 2013). However, this will lead to grain growth of the metallic matrix, which may result in decrease in strength of the MMCs. In order to reduce the adverse effects of the heating process, researchers have developed some novel sintering methods, like spark plasma sintering (SPS) and microwave sintering.

Fig. 2 Schematic diagram showing the sintering stages. Reproduced from Gupta, M., Sharon, N.M.L., 2011. *Magnesium, Magnesium Alloys, and Magnesium Composites*, first ed. New Jersey: John Wiley & Sons.

Fig. 3 A schematic view of the SPS apparatus and its components. Reproduced from Azarniya, A., Azarniya, A., Sovizi, S., *et al.*, 2017. Physicomechanical properties of spark plasma sintered carbon nanotube-reinforced metal matrix nanocomposites. *Progress in Materials Science* 90, 276–324.

Spark plasma sintering

SPS is a typical field assisted sintering technique, which can achieve fully dense compacts by using low processing temperature and short sintering time. Thus, it has attracted more and more attentions for fabricating MMCs, especially for MMCs with nano grains (Azarniya *et al.*, 2017). Fig. 3 shows the schematic of the SPS process. In this technique, the direct current (DC) pulse discharge could generate spark plasma, Joule heating, and an effective electrical field diffusion effect. In addition, the application of pressure

Fig. 4 Schematic diagram of the hybrid microwave heating experimental setup used. Reproduced from Gupta, M., Sharon, N.M.L., 2011. *Magnesium, Magnesium Alloys, and Magnesium Composites*, first ed. New Jersey: John Wiley & Sons.

can further promote the consolidation of the materials. Therefore, the nanostructure features of MMCs obtained from ball milling can be preserved by preventing or at least minimizing grain growth through careful control of the SPS parameters, which is promising to achieve superior mechanical properties. Nowadays, SPS has been employed to fabricate a large number of MMCs, and the metallic matrices include Cu, Al, Ag, Ni, Ti, Mg, and Ni (Azarniya *et al.*, 2017).

Microwave sintering

Another novel method is microwave sintering. Heat is generated from within the materials and radiates to the outer surface due to the penetrative power of microwaves. Thus, the temperature of the core of the materials is higher than that of the surface during pure microwave heating. Accordingly, the resulted surface of the MMCs might be relatively poor. In order to overcome the shortcomings of either conventional heating or pure microwave heating, Gupta's research group developed a microwave assisted hybrid sintering technique (Gupta and Wong, 2015), and the hybrid heating experimental setup is as shown in Fig. 4. This method involves a pre-calibrated temperature exposure near the melting point of the metallic matrix in a microwave oven using SiC as the microwave susceptor material. This can provide a more uniform temperature gradient within the billet. In addition, this technique can reduce more than 80% in the sintering time and energy consumption when compared to conventional sintering while realizing higher mechanical properties of the composites. An important difference between the various sintering techniques is that hybrid microwave sintering can be carried out in air without any inert protective atmosphere, while conventional sintering should be conducted in an Ar atmosphere to minimize oxidation. It is worth noting that the end mechanical performance of the hybrid microwave sintered MMCs are not compromised when compared to their conventionally sintered counterparts (Gupta and Wong, 2005). Therefore, this hybrid sintering method is economically viable for industries and is friendly to environment (Wai *et al.*, 2010).

Novel Methods

As mentioned above, both of blending and high energy ball milling in conventional PM have their limitations. The former one is hard to disperse nano reinforcements, while the latter dispersing method will damage the structural integrity of the nano carbon materials. Therefore, more and more attentions have been focused to develop some novel methods, which can uniformly disperse nano reinforcements in metallic matrix and effectively maintain their structural integrity, mainly for CNTs and GNPs. Following sub-sections will systematically introduce some useful techniques which are based on PM, including: (1) semi-powder metallurgy, (2) flake powder metallurgy, (3) molecular level mixing, and (4) in-situ synthesis.

Semi-powder metallurgy

Semi-powder metallurgy involves blending reinforcements and metal powders in slurry, where mechanical stirring and ultrasonication are usually used, and then the powder mixture of the MMC can be obtained after drying in a vacuum drying oven. Subsequent steps are always the same as conventional PM and thus this technique is called semi-PM. Its schematic diagram is shown in Fig. 5. This method can achieve uniform dispersion of CNTs and/or GNPs, which are difficult to disperse by blending, due to the significant effect of ultrasonication. Better results can be obtained, when dispersants for CNTs or GNPs are employed. In addition, the special structure of CNTs or GNPs is perfectly maintained during dispersion process, resulting in an excellent strengthening efficiency.

Fig. 5 Schematic of semi powder metallurgy method. Reproduced from Rashad, M., Pan, F.S., Tanga, A., *et al.*, 2014. Synergetic effect of graphene nanoplatelets (GNPs) and multi-walled carbon nanotube (MW-CNTs) on mechanical properties of pure magnesium. *Journal of Alloys and Compounds* 603, 111–118.

Flake powder metallurgy

Another novel method is flake powder metallurgy. As indicated earlier, the severe impact of balls can damage the structural integrity of CNTs or GNPs during the long-time high energy ball milling process which ultimately affects the mechanical properties. To solve this problem, [Xu *et al.* \(2017\)](#) proposed a novel flake powder metallurgy via shift-speed ball milling (SSBM), namely, the combination of long-time low speed ball milling (LSBM) and short-time high speed ball milling (HSBM). The collision force in planetary ball mill could be divided into two types: (1) radial component of compressing force, and (2) tangential component of shearing force ([Cundall and Strack, 1979](#); [Dallimore and McCormick, 1996](#); [Chattopadhyay *et al.*, 2001](#)). The former one mainly contributes to powder deformation such as flattening, cold-welding and fragmenting, while the latter one can effectively disperse the nano reinforcements ([Suryanarayana, 2001](#); [Andrews *et al.*, 2002](#)). To note that both compressing force and shearing force would increase notably as the milling speed increases, leading to significant increase in collision force, which determined the co-deformation and dispersion mechanisms of composite powder mixtures. During LSBM, the mild compressing force would take a long time for the spherical Al powders to become flakes, thus, the shearing force can have enough time to gradually break up the big clusters of CNTs or GNPs and achieve uniform distribution of them on the surface of metal flakes. In HSBM stage, the significantly increased collision force would accelerate the powder flattening and cold welding, which can promote the interfacial bonding between metal powders ([Fig. 6\(a\)](#)). Besides, the damage of the structural integrity of CNTs and GNPs can be acceptable due to the low collision force during LSBM and short period during HSBM. This method has been employed to fabricate Al matrix composites containing CNTs ([Xu *et al.*, 2017](#)) and GNPs ([Jiang *et al.*, 2018](#)), respectively. [Fig. 6\(b\)–\(d\)](#) show the TEM images of the uniform dispersion and structural integrity of CNTs in Al matrix, and the results of mechanical properties compared to other works also revealed that the CNT/Al matrix composites by this SSBM flake PM method has balanced strength and ductility.

[Jiang *et al.* \(2011, 2012\)](#) proposed another new flake PM method. The processing steps of this method are shown in [Fig. 7\(a\)](#). Firstly, nanoflakes of Al were prepared by using high speed ball milling, and then the Al nanoflakes were modified by polyvinyl alcohol (PVA), which can be decorated with hydroxyl groups ($-OH$). The CNTs functionalized with carboxyl groups ($-COOH$) were dispersed in sodium dodecyl benzene sulfonate (SDBS) solution, and then the PVA-modified Al nanoflakes were added into the CNTs suspension. After blending in the slurry, the CNTs were adsorbed onto the surfaces of Al nanoflakes through hydrogen bonding between $-COOH$ groups and $-OH$ groups, resulting in a uniform dispersion of CNTs on the surfaces of Al powders with

Reproduced from Li, Z., Fan, G.L., Guo, Q., *et al.*, 2015. Synergistic strengthening effect of graphene-carbon nanotube hybrid structure in aluminium matrix composites. Carbon 95, 419–427.

very little structure damage (Fig. 7(c)). The composite powders were then obtained by vacuum drying and heating in a flowing Ar atmosphere at high temperature to remove the PVA. The subsequent steps remain similar to that of conventional PM. Finally, the high strength and remarkable strengthening efficiency (Fig. 7(d) and (e)) were mainly attributed to the homogeneous and individual distribution of CNTs in Al matrix and their retained structural integrity.

Li *et al.* (2015) developed a similar and improved flake PM method (as shown in Fig. 8(a) and (b)). The main difference is that dispersion of hybrid CNTs and RGO were assisted by electrostatic adsorption rather than hydrogen bonding. Uniform dispersion

and the maintained structural integrity of hybrid CNTs and RGO were also both obtained (Fig. 8(c)–(e)). Thus, high mechanical performance and strengthening efficiency were achieved (Fig. 8(f) and (g)). It is worth noting that a planar RGO-CNTs network architecture in the composites was formed due to π - π interaction, leading to a significantly higher strengthening efficiency of hybrid GNPs-CNTs than those of individual RGO or CNT reinforcement. The similar technique has also been used to fabricate graphene reinforced Cu matrix composite with high performance (Yang *et al.*, 2018; Yang *et al.*, 2017).

For magnesium alloy matrix composites, the flake powder metallurgy method may be inappropriate due to the strong chemical activity of Mg as it could be severely oxidized during the slurry blending and electrostatic adsorption process (Xiang *et al.*, 2019a,b). Thus, Zhou *et al.* (2019) made some improvements on the basis of the methods mentioned above and developed another PM route which is efficient and suitable for Mg matrix to prepare multi-scale hybrid micron SiC and CNTs reinforced Mg matrix composites (Fig. 9(a)). This route involves a multi-step dispersion process. First, the CNTs were uniformly adsorbed onto the surface of the SiC (Fig. 9(b) and (c)) through hydrogen bonding between the carboxyl (–COOH) groups and hydroxyl (–OH) groups, which were decorated on the surfaces of the CNTs and SiC, respectively. Then, shift-speed ball milling was employed to achieve a uniform dispersion of the hybrid reinforcements in the end composites. In this route, the micron SiC particles can act as carrier to transfer the CNTs from the surface of the SiC into the matrix. Because micron size SiC particles can be easily dispersed in metallic matrix uniformly via ball milling, the ball milling time needed to disperse CNTs uniformly in the matrix can be much shorter than common ball milling methods. Therefore, this route can significantly improve the dispersion efficiency of the CNTs in the matrix. In addition, the shorter ball milling time can also contribute in maintaining the structural integrity of CNTs. By ensuring structural integrity of reinforcement and uniform dispersion of multi-scale hybrid reinforcements in the Mg matrix (Fig. 9(e)–(g)), good combination of ultra-high strength and good ductility was successfully achieved (Fig. 9(h)).

Molecular level mixing

Molecular level mixing is a composite powder preparation technique, especially for composite containing CNTs or GNPs, and as the name suggests, the dispersion of the nano reinforcements is achieved on the molecular level by using this technique (Bakshi *et al.*, 2010). Fig. 10 shows the schematic of molecular-level mixing process for preparing Cu-CNT composite powders. The method involves acid treatment and functionalization of the CNTs before introducing them into copper salt ($\text{Cu}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$) solution, which can promote the CNT suspension and surface metal deposition on their surface. The treated CNTs are then added into the Cu salt bath and dispersed by using ultrasonication to prepare the CNT-Cu ion precursor. Subsequently, the precursor would undergo drying, calcinations and a reduction process to produce Cu-CNT composite powders. It is worth noting that the reduction process can also be conducted by using reducing agents directly in the bath to shorten the preparation time (Xu *et al.*, 2007). Finally, conventional PM route are always employed to fabricate bulk MMCs for these nanocomposite powders prepared by molecular-level mixing technique. In addition to Cu-CNT system, Chen *et al.* (2003) synthesized Sb/SbSn0.5-CNT nanocomposite for anode materials in Li-ion batteries. The formation of a semi-continuous layer of metal on CNTs was reported by these authors.

The advantage of molecular-level mixing technique is that it has great potential to improve dispersion and interfacial bonding strength of the nano-reinforcements such as CNTs and GNPs with metal matrix, as well as, maintaining the structural integrity of these reinforcements. However, this method can only be applied to metallic matrix with weak reducibility like Cu, and Au and thus there are only a few studies of this method reported until now.

In-situ synthesis

In-situ methods involves synthesis of MMCs in which the reinforcements are generated in a metallic matrix by using chemical reactions between elements or between elements and compounds during the fabrication process of the composites (Tjong and Ma, 2000). Moreover, compared to the MMCs fabricated by using ex-situ processing techniques, the in-situ MMCs have three main merits (Tjong and Ma, 2000): (1) the reinforcements formed by in-situ reactions are thermodynamically stable in the metallic matrix, which can be employed in elevated-temperature services, (2) a good interfacial bonding can be achieved due to the clean interface between in-situ reinforcements and metallic matrix and (3) the in-situ formed reinforcements are always fine in size and distribute more homogeneously in metallic matrix when compared to ex-situ reinforcements. Therefore, the in-situ MMCs exhibit superior room and elevated temperature mechanical performance due to the above-mentioned advantages and hence have the great potential for widespread applications. Thus, more and more attention has been paid to develop new techniques and optimizing processing parameters for in-situ methods during the past decades. According to the different types of in-situ reinforcements, we categorized two groups of in-situ techniques: (1) in-situ ceramic phases, and (2) in-situ carbonaceous materials.

For in-situ ceramic phases, a number of reactive systems have been investigated during the past three decades. And Al, Ti, C and B are four most frequently used elements. There are six typical reactive systems, namely, Al-Ti-C, Al-Ti-B, Ti-C, Ti-B₄C, Ti-TiB₂, and molten salt systems. These are summarized in Table 1. For PM route, the first five systems are often used. Ball milling is usually utilized to disperse the reactants or compounds uniformly onto the surfaces of metallic matrix powders. In this step, in order to avoid severe plastic deformation and oxidation, the appropriate parameters of ball milling should be employed (Wei *et al.*, 2018). The milled mixtures are subsequently compacted or hot-pressed and sintered at optimized parameters obtained via thermodynamic and kinetic calculations as well as experimental verifications. Ma *et al.* (1996) fabricated in-situ hybrid Al₂O₃ and TiB₂ particulates reinforced Al matrix composites with superior mechanical properties by using powder metallurgy technique. High

performance of the composite was attributed to the uniform distribution of the fine and equiaxed in-situ Al₂O₃ and TiB₂ particulates in Al matrix (Fig. 11(a)) and the clean interfaces between the in-situ reinforcements and Al matrix (Fig. 11(b)).

For Ti matrix composites, the network structures could be formed by in-situ reaction during hot pressing. Wei *et al.* (2018) reported that the in-situ powder metallurgy method can be conducted to prepare hybrid in-situ Ti alloy matrix composites with enhanced high-temperature oxidation resistance due to formation of hybrid (TiC particles + TiB whiskers) networks (as shown in Fig. 12). Even a tailored two-scale architecture can also be achieved in Ti6Al4V composites (Liu *et al.*, 2015). The microstructure

Fig. 13 (a) SEM micrograph (low magnification) of the composite, (b) SEM micrograph of the magnified region I, (c) secondary-scale architecture in intergranular β phase (Ti_5Si_3 needles), and (d) the tensile stress-strain curves of 0.5, 1.0, 2.0, 5.0, 8.0 vol%, $(\text{TiC} + \text{Ti}_3\text{SiC}_2 + \text{Ti}_5\text{Si}_3)/\text{Ti}_6\text{Al}_4\text{V}$ composites. Reproduced from (d) Liu, C., Huang, L.J., Geng, L., Jiao, Y., Tang, A., 2015. In situ synthesis of $(\text{TiC} + \text{Ti}_3\text{SiC}_2 + \text{Ti}_5\text{Si}_3)/\text{Ti}_6\text{Al}_4\text{V}$ composites with tailored two-scale architecture. *Advanced Engineering Materials* 17 (7), 933–941.

and tensile properties of these composites are shown in Fig. 13. The first-scale tailored architecture is the network formed by in-situ Ti_3SiC_2 bars and near equiaxed TiC particles (Fig. 13(a) and (b)), and the secondary-scale architecture is the ultrafine Ti_5Si_3 needles precipitated in intergranular β phase, which was distributed in center matrix particles (Fig. 13(c)). Due to the unique two-scale architecture, the strength of the hybrid $\text{Ti}_6\text{Al}_4\text{V}$ composites were effectively enhanced while maintaining good ductility (8.5%) when the volume fraction of the hybrid reinforcements reached 5 vol% (Fig. 13(d)).

In-situ synthesis of carbonaceous nanomaterials such as CNTs and GNPs in MMCs is an innovative and effective strategy to fabricate advanced MMCs with high performance. This method ensures homogenous dispersion and perfect structural integrity of the carbon nanomaterials after the fabrication process (Tjong, 2013). Powder metallurgy route is usually employed to fabricate these MMCs with in-situ carbon-based nano-reinforcements. According to the different types of the carriers for the in-situ carbonaceous materials, this technique can be categorized into two groups: (1) the direct synthesis of carbon nanomaterials on metal matrix powders (Yang *et al.*, 2011) and (2) synthesis of carbon nanomaterials on the ceramic carriers, such as SiC and Al_2O_3 particles, and then their transfer into the matrix (Li *et al.*, 2014). The former also has two different methods. For transition metal matrix, such as Cu, Fe, Co and Ni, the in-situ carbonaceous nanomaterials can be directly synthesized on these metal powders without using additional catalyst (Tjong, 2013). However, for other metallic matrices without catalytic function, such as Al (He *et al.*, 2007) and Mg (Sun *et al.*, 2013), the additional catalyst should be used to assist the growth of the carbon nanomaterials on the surface of metal powders. The schematic illustration of such a typical fabrication process is shown in Fig. 14(a). This route always involves several steps, first, the additional catalyst particles are decorated on the metal powders through impregnation in the transition metal salt solution followed by drying and calcination in the protective atmosphere. The second step involves in-situ synthesis of the carbon nanomaterials, like CNTs, on metal powders by CVD. Finally, the composites powders containing in-situ carbon materials are compacted, sintered and hot extruded. Sometimes, ball milling is also employed to further disperse these in-situ nano-reinforcements and to promote a better interfacial bonding between metal powders (Yang *et al.*, 2013).

Fig. 14 Schematic illustration of the fabrication procedure of in-situ carbon nanomaterials reinforced MMCs: (a) metal powder carrier, (b) ceramic particle carrier. Reproduced from (a) Yang, X.D., Liu, E.Z., Shi, C.S., *et al.*, 2013. Fabrication of carbon nanotube reinforced Al composites with well-balanced strength and ductility. *Journal of Alloys and Compounds* 563, 216–220. (b) Li, S.S., Su, Y.S., Ouyang, Q., Zhang, D., 2016a. In-situ carbon nanotube-covered silicon carbide particle reinforced aluminium matrix composites fabricated by powder metallurgy. *Materials Letters* 167, 118–121. Li, S.S., Su, Y.S., Zhu, X.H., *et al.*, 2016b. Enhanced mechanical behaviour and fabrication of silicon carbide particles covered by in-situ carbon nanotube reinforced 6061 aluminium matrix composites. *Materials & Design* 107, 130–138.

Utilizing micron ceramic particles as the carrier of in-situ carbon nanomaterials is a promising way to fabricate advanced multi-scale hybrid reinforcements containing MMCs with excellent properties. The schematic is shown in [Fig. 14\(b\)](#), and the process is similar to that of metal powder carrier. The main difference is that the catalyst particles are attached on the surface of the ceramic particle reinforcements rather than on metal matrix powders. Hybrid in-situ CNTs and SiC particles reinforced Al matrix composites ([Li *et al.*, 2016a,b](#)) and hybrid in-situ CNTs and Al_2O_3 particles reinforced Mg matrix composites ([Li *et al.*, 2014](#)) have been successfully prepared by this method, and high mechanical performance of both these types of MMCs were reported.

A novel in-situ method was also proposed to fabricate well-dispersed 3D graphene (GN)/carbon nanotubes hybrid copper nanocomposites ([Zhang *et al.*, 2017a,b,c](#)). [Fig. 15](#) shows the schematic diagram of this innovative method. This method involves in-situ synthesis of 3D graphene network and molecular level mixing. First, the CNTs functionalized with $-\text{COOH}$ were dispersed in the solution of $\text{C}_6\text{H}_6\text{O}_6\text{-Cu}(\text{NO}_3)_2\text{-NaCl}$ under ultrasonication followed by rapid freezing using liquid nitrogen to avoid agglomeration of CNTs. Then, the assembled powders of CNTs- $\text{C}_6\text{H}_6\text{O}_6\text{-Cu}(\text{NO}_3)_2\text{-NaCl}$ were obtained by using the freeze-drying technology. Next, the assembled powders were calcinated and cooled rapidly to room temperature under H_2 atmosphere. The calcinated powder were subsequently washed with deionized water to obtain 3D CNT-GN@Cu powders. The 3D CNT-GN@Cu powders were further coated with copper through an impregnation-calcination-reduction process to achieve a uniform dispersion of 3D CNT-GN in Cu powders. Finally, the 3D CNT-GN/Cu bulk composite was produced by SPS method. A superior combination of strength and ductility was successfully achieved due to the well-dispersed 3D network structure of hybrid CNTs and GN by using this in-situ and molecular level mixing strategy.

Thermo-Mechanical Processing (TMP)

TMP is the set of heating and shaping operations capable of converting traditional materials into high-quality components with enhanced properties ([Verlinden *et al.*, 2007](#)). In general, there are always two direct consequences during TMP: the first one is the desired shape change at macroscopic level, and the other one is the microstructural change on a micro scale. In most cases, TMP can refine grains and eliminate defects, such as shrinkage and pores formed during fabrication process, of metallic materials, resulting in a significantly enhanced mechanical performance. It should be noted that the improvement of microstructure is heavily dependent on processing parameters including temperature, strain, strain rate, deformation mode, lubricants, etc.

TMP is an important secondary processing method to improve mechanical properties of MMCs irrespective of whether they are fabricated by solid phase or liquid phase methods. In particular, for MMCs prepared by liquid phase technique, their strength and ductility can be both improved after TMP. According to the degree of the accumulative deformation and grain refinement, we can divide the TMP conducted on MMCs into two types: (1) conventional plastic deformation, and (2) severe plastic deformation.

Conventional Plastic Deformation

As for conventional plastic deformation, there are three commonly used methods, namely, extrusion, rolling and forging. These processing methods are usually conducted at elevated temperatures due to the limited ductility of most of the MMCs.

Extrusion

Extrusion is the most commonly used secondary processing method for MMCs, in which a billet of the MMCs is first placed into an extrusion chamber with a die at one end and a ram on the other. Through the application of force, the billet undergoes a gradual reduction in area through the relatively narrow die to obtain long profiles of constant section determined by the die geometry. **Fig. 16** shows three types of extrusion, namely, direct, conventional, and hydrostatic. In direct extrusion, there is a dead zone near the die where the extruded materials cannot flow. In conventional extrusion, the die is modified to minimize the dead zone, however, the tapered die generates die friction more easily than that of flat die, leading to higher deformation stress at the MMCs/die interface, which may result in material discontinuities like ragged edges. To solve the problem of dead zone and material discontinuities, hydrostatic extrusion is proposed by conducting the extrusion inside a high-pressure fluid. A nearly hydrostatic state and minimal effect of friction in the billet can be achieved in this high-pressure fluid due to the minimized contact area between materials and die.

There are three important factors that need to be critically controlled during extrusion. These include: (1) extrusion ratio, (2) extrusion temperature, and (3) extrusion speed. These factors can significantly affect the mechanical performance of the final extruded MMCs. Wang *et al.* (2011) and Tun and Gupta (2008) found that the distribution of reinforcements whether micron SiC particles or nano Y₂O₃ particles in Mg matrix composites can be improved as the extrusion ratio is increased. In addition, for nano Y₂O₃/Mg composites fabricated by PM, the increased extrusion ratio also reduced the porosity as well as refined grains, leading to enhanced mechanical properties. Extrusion temperature has strong effect on dynamic recrystallization (DRX) of the

Fig. 16 Three types of extrusion processing: (a) direct, (b) conventional, and (c) hydrostatic. Reproduced from Chawla, N., Chawla, K.K., 2013. *Metal Matrix Composites*, second ed. New York: Springer.

metallic matrix during extrusion. If the extrusion temperature is too low, DRX procedure will not be completed, resulting in many large grains after extrusion; however, high extrusion temperature would induce significant growth of grain size, which has been demonstrated in micron SiC reinforced AZ91 alloy composites (Wang *et al.*, 2011). Extrusion speed can also influence the final mechanical properties of MMCs. Sun *et al.* (2018) investigated the effects of extrusion speed on the mechanical properties and microstructure of the SiCp/AZ91 composite. They revealed that decreasing the extrusion speed (from 1.0 mm/s to 0.01 mm/s) could significantly enhance both yield strength (YS) and ultimate tensile strength (UTS) mainly due to the refinement of the grains and $\text{Mg}_{17}\text{Al}_{12}$ phases precipitates. However, the ductility dropped dramatically which also limited the application of this material. In addition, some researchers have focused on the optimization of extrusion die parameters. For example, Huang *et al.* (2016) investigated the effects of extrusion dies angle on the microstructure and properties of $(\text{TiB} + \text{TiC})/\text{Ti}_6\text{Al}_4\text{V}$ in situ Ti matrix composites. They stated that both tensile strength and ductility were reduced as the extrusion dies angle increased from 45° to 75° , and suggested that the optimal extrusion dies angle should be less than 60° .

Rolling

Rolling is the most important metal working and shaping technique from an economic point of view due to its high productivity. It is used to produce flat and sheet shape components of almost all kinds of common metallic materials, such as steel and aluminum, for a long period. This technique basically involves pushing a metal work-piece into the gap between two rotating rolls, and then the two rolls will simultaneously draw the workpiece and compress it to decrease the thickness and increase the length (as-shown in Fig. 17). Rolling temperature, rolling passes, single pass reduction, and rolling speed are four important factors which can determine the enhancement of mechanical properties during rolling process.

For MMCs, rolling is also one of the important and common TMP methods. Most MMCs are treated by hot rolling due to their limited ductility, but for some MMCs with good ductility, cold rolling is also feasible. This technique is employed to process Al (Kumar *et al.*, 2018), Mg (Liu *et al.*, 2017), Ti (Huang *et al.*, 2012), and Cu (Wang *et al.*, 2020) matrix composites, in which the mechanical properties of these MMCs were all enhanced. Wang *et al.* (2018) systematically investigated the effects of rolling passes and temperatures on the microstructure and mechanical properties of SiCnp/AZ31 nanocomposite. Their results revealed that the matrix grains were refined by progressive DRX, which was enhanced continuously with the increase of rolling passes (reduction). They also found that the nano particles could delay and inhibit the formation of shear bands when compared to AZ31 alloy. The percentage of DRX was improved and the formation of shear bands could be further inhibited as the rolling temperature increased. For mechanical performance, with the increase of the rolling passes, the yield strength enhanced slightly, while the elongation increased first and then decreased. For the sheets with the same rolling reduction, the yield strength reduced and the elongation improved as the rolling temperature increased.

Forging

Forging is the oldest of the metal forming process which can be traced back to 5000–8000 BCE and is also a common TMP method for MMCs including Al (Jin *et al.*, 2020), Mg (Deng *et al.*, 2011) and Ti (Yang *et al.*, 2020) matrix composites. The forging techniques can be roughly categorized into two types: (1) free forging and (2) die forging. The latter one includes several types: (1) open-die forging, (2) closed-die forging, (3) rotary swaging, and (4) rotary forging (Verlinden *et al.*, 2007).

Severe Plastic Deformation

The conventional TMP methods mentioned above cannot be used to produce materials with ultrafine grains (UFG, average grain size less than $\sim 1 \mu\text{m}$) due to the limitation on the overall strains. Accordingly, attention has been focused on the development of novel techniques which can prepare ultrafine-grained materials with grain sizes in the sub-micrometer and the nanometer range. To achieve this goal, there are two different approaches, namely, (1) “bottom-up” route and (2) “top down” route. In the bottom-up approach, UFG materials are obtained by assembling individual atoms or by consolidating nanoparticle solids. The top-down approach relies on imposing large amount of strain or shock loading, which can avoid the small product sizes and the contamination when compared to the bottom-up approach.

Formally, the main feature of severe plastic deformation (SPD) is that very high strain is imposed on a bulk material without any significant change in the overall dimensions of the material resulting in excellent grain refinement. To date, many different SPD processing techniques have been developed, and for MMCs, equal channel angular pressing (ECAP), high-pressure torsion (HPT), accumulative roll bonding (ARB), friction stir processing (FSP), cyclic extrusion and compressing (CEC), and multi-directional forging (MDF) have been extensively reported.

Equal channel angular pressing

The ECAP was first introduced in the 1970s and 1980s to develop a metal forming process where high strains can be imposed into metal billets by simple shear. However, the potential of this method for preparing UFG materials was not exploited until 1990s (Valiev and Langdon, 2006). Similar to conventional TMP methods, the mechanical properties of ECAPed materials are also strongly affected by pressing passes, pressing temperature, pressing speed, and the die parameters including the channel angle (Φ) and the angle of curvature (Ψ) (as shown in Fig. 18(a)). The main difference is that the processing routes in ECAP also have significant effects on the microstructure evolution and mechanical properties of the final billets. There are four basic processing routes which are illustrated in Fig. 18(b). From extensive studies, the results revealed that route Bc might be the superior one to realize homogenous microstructure.

More and more attentions have been paid to utilize ECAP for processing MMCs. The effects of ECAP on microstructure evolution and mechanical properties of Al (Ramu and Bauri, 2009), Mg (Qiao *et al.*, 2016), Ti (Han *et al.*, 2015), and Cu (Wang *et al.*, 2013) matrix composites have been investigated. Similar conclusions could be drawn that intense plastic strain introduced by ECAP has a potential for both refining the grain size of metal matrix (even to submicrometer or nano meter level) and in significantly improving the strength of the composites. In some cases, the strength and ductility were enhanced simultaneously by choosing suitable processing parameters. In addition, there are also some interesting phenomena: (1) ECAP can effectively improve the homogeneity of the distribution of nano-reinforcements due to large shear force thus leading to an enhancement in mechanical properties of an MMC with clusters of reinforcements (Sabirov *et al.*, 2005) and (2) although large shear force was introduced during ECAP, there was little or no breaking of the particulates, like Al_2O_3 , after processing. The minimized cracking possibility of particulates might be attributed to no confining aperture and thus no reduction in the sample cross-section as it passes through the die (Valiev *et al.*, 1998).

High-pressure torsion

HPT is another important “top-down” SPD technique which has similar mechanical performance enhancing effects as that of ECAP. Its schematic diagram is as shown in Fig. 19. The disk sample is located between two anvils where it is subjected to a

compressive applied pressure, P , of several GPa at room temperature or at an elevated temperature and simultaneously it is subjected to a torsional strain which is imposed through rotation of the lower anvil. Surface frictional forces therefore deform the disk by shear so that deformation proceeds under a quasi-hydrostatic pressure (Zhilyaev and Langdon, 2008). In this technique, the final properties of the processed materials are strongly dependent on the applied load and the number of rotations (the imposed strain).

This technique has also been utilized to refine matrix grains and to optimize the distribution of reinforcements for Al (Valiev *et al.*, 1998), Mg (Chen *et al.*, 2015), Ti (Li *et al.*, 2018), and Cu (Islamgaliev *et al.*, 2001) matrix composites. In particular, Chen *et al.* (2015) applied HPT to improve the mechanical performance of Mg-2Zn composite containing 14 vol% nano SiC particles.

Fig. 20 Schematic procedure to produce MMCs via ARB process. Reproduced from Baazamat, S., Tajally, M., Borhani, E., 2015. Fabrication and characteristic of Al-based hybrid nanocomposite reinforced with WO_3 and SiC by accumulative roll bonding process. *Journal of Alloys Compounds* 653, 39–46.

After HPT processing, this material achieved remarkable yield strength of 710 ± 35 MPa (the highest yield strength reported for Mg based materials). In addition, the plastic strain of over 40% was also obtained, indicating an excellent combination of ultrahigh strength and ductility of this HPTed composite. Therefore, this method has great potential to be used for improving energy efficiency and system performance in numerous applications.

Accumulative roll bonding

ARB processing is another novel SPD method, also known as sandwich processing, which can be used to produce MMCs with ultra-fine grains (Ghalehbandi *et al.*, 2019). Fig. 20 shows steps involved in ARB and include: (1) annealing the metal strips or sheets, (2) surface preparation through degreasing by acetone and scratching with a steel brush, (3) adding reinforcements, (4) stacking, and (5) roll bonding. In the third step, the reinforcements, especially nano-reinforcements, are usually dispersed in the dispersion solution, and subsequently sprayed onto the surfaces of the metal strips or sheets followed by drying in the air (Yoo *et al.*, 2012). Electrophoretic deposition can also be used to disperse the reinforcements onto the metal strips, which has been demonstrated in the study on CNTs reinforced Mg (Xiang *et al.*, 2019a,b) and Cu (Meng *et al.*, 2018) matrix composites prepared by electrophoretic deposition and hot rolling. Baazamat *et al.* (2015) produced hybrid WO_3 and SiC nanoparticles reinforced Al matrix nanocomposites through ARB process, and the results revealed that after 9 cycles, the hybrid nanocomposites exhibited an excellent distribution of the nanoparticles with good interfacial bonding between the reinforcements and the matrix. This technique may become popular for fabricating advanced MMCs with high performance due to its ease of processing (Bakshi *et al.*, 2010).

A unique technology combining anodizing and accumulative rolling bonding is used to fabricate in-situ Al_2O_3 reinforced Al matrix composites. This method always involves the following steps: (1) the Al strips are anodized to form in-situ Al_2O_3 on the surfaces of the strips after annealing treatment followed by degreasing, (2) dispersion of the ex-situ reinforcements on the surfaces of the anodized Al strips uniformly, (3) the surface preparation for non-anodized Al strips, (4) stacking of the anodized Al strips with ex-situ reinforcements and non-anodized Al strips and (5) accumulative rolling bonding. Hybrid $\text{Al}_2\text{O}_{3\text{in-situ}} + \text{ZrC}_{\text{ex-situ}}$ (Shamanian *et al.*, 2015), $\text{Al}_2\text{O}_{3\text{in-situ}} + \text{CNTs}_{\text{ex-situ}}$ (Nasresfahani and Shamanian, 2018), $\text{Al}_2\text{O}_{3\text{in-situ}} + \text{TiC}_{\text{ex-situ}}$ (Farajzadeh Dehkordi *et al.*, 2013), and $\text{Al}_2\text{O}_{3\text{in-situ}} + \text{SiC}_{\text{ex-situ}}$ (Ahmadi *et al.*, 2013) reinforced Al matrix composites were successfully fabricated using this method.

Friction stir processing

Friction stir processing, derived from the modification of friction stir welding, is a novel severe plastic deformation (SPD) technique. The main idea of this method is to disperse reinforcements uniformly in metallic matrix and refine grain size via the rotation of tool pin. To produce MMCs, there are two ways to place the reinforcements. A long groove is cut on the surface of the metallic matrix in the path of tool followed by filling with reinforcements and treating with FSP as shown in Fig. 21(a). Alternatively, reinforcements are introduced into the cavities drilled in a metallic plate followed by FSP as shown in Fig. 21(b). Eskandari *et al.* (2016) successfully fabricated hybrid TiB_2 particles and Al_2O_3 particles reinforced Al matrix composites using FSP and found that the wear resistance of

Fig. 21 Schematic diagram of FSP using different reinforcements incorporating methods: (a) grooves and (b) cavities. Reproduced from (a) Jain, V.K.S., Yazar, K.U., Muthukumar, S., 2019. the processed hybrid nanocomposites over the un-reinforced matrix alloy was improved by more than eight times due to the homogeneous distribution of the hybrid reinforcements. A similar result was also reported in a study on hybrid ZrSiO_4 and Al_2O_3 reinforced Mg matrix composites prepared by using FSP (Sharifitabar *et al.*, 2016). Moreover, FSP is also an effective technique for secondary mechanical treatment for the MMCs in order to obtain uniform distribution of reinforcements, especially nano-reinforcements, like CNTs (Liu *et al.*, 2014) or GNPs (Ajay Kumar *et al.*, 2020), in the metallic matrix.

Cyclic extrusion and compression

Fig. 22 shows the schematic diagram of CEC technique. The characteristics of this method are as follows: (1) extrusion and compression can be carried out simultaneously, which is helpful to eliminate the defects in the billets; (2) the compressive stress state can prevent the crack initiation and growth; (3) it can be processed continuously without changing the original shape of the billets; (4) the large strain imposed by CEC can lead to a remarkable refinement of grains. This technique has a wide range of applications, and it can be directly used to process ingots or powders to obtain bulk materials with fine grains and excellent mechanical properties. This method is also used to improve the mechanical performance of CNTs/Mg (Zhang *et al.*, 2017a,b,c) and SiC/Mg (Guo *et al.*, 2012) composites.

Multi-directional forging

MDF is a simple SPD technique. The schematic illustrations of MDF is shown in Fig. 23. From the figure, it can be seen that the direction of applied load changes along the three axial directions of the billets during MDF processing. The billet is deformed repeatedly according to the direction of the applied load, but its dimension nearly stays unchanged. Thus, the essence of MDF is multi-pass free forging in different directions along the billets. This method is successfully used for the optimization of mechanical properties for Mg (Nie *et al.*, 2015) and Ti (Lü *et al.*, 2019) matrix composites.

Summary and Outlook

This article illustrates that solid phase processing techniques can fabricate MMCs with fine (even ultrafine) grains, homogeneous distribution of reinforcements and appropriate interfacial bonding, thus, resulting in high mechanical performance. It is

undeniable that this field has been instrumental in realizing significant achievements in recent times. However, there are still some big challenges which can hinder the wide applications of these technologies in the field of MMCs. Compared with liquid phase approach, the solid phase approaches involve more complicated steps and lower mass production capability leading to much higher cost of production. In addition, for nano metal matrix composites (NMMCs), the content of the nano-reinforcements, such as nano ceramic particles, CNTs and GNPs, still remained at a relatively low level (usually less than 5 vol%) due to the action of strong van der Waals' forces, which strongly limits the significant enhancement in mechanical properties of NMMCs. Therefore, researchers may need to pay more attention to the following two aspects: (1) simplify the preparation process of solid phase techniques to effectively improve the economics of the process. For example, some simulation methods or machine learning or artificial intelligence can be employed for preliminary exploration to decrease the number of attempts and reduce experimental costs and (2) in order to achieve high volume fraction of uniformly dispersed nano-reinforcements in metallic matrix, some novel and efficient dispersing methods can be further explored.

Introduction

A composite material is a combination of two or more insoluble components having different chemical composition and often various shape. [Mazumdar \(2010\)](#) The continuous phase is referred to as the matrix while the discontinuous phase is referred to as the reinforcement. These two independent components often have noticeable differences in their properties spanning mechanical, physical, electrical and even chemical. One of the components, often the matrix, will be tough and ductile while the other component, namely the reinforcing phase will be light, strong and hard and intrinsically brittle. The metal matrix is often a pure metal or its alloy counterpart and is the continuous phase while the reinforcing phase can be (1) discontinuous in the form of particulates (i.e., particles), short fibers and whisker, and (2) continuous in the form of fibers. This is shown in [Fig. 1](#).

The primary and most desirable need is for the metal matrix composites (MMCs) to offer a healthy combination of properties to include low density, high or adequate strength both in tension and in compression, good thermal expansion characteristics, acceptable creep resistance, good resistance to friction, and overall good wear behavior. ([Ozben et al., 2008](#); [Verma et al., 2017](#); [Sri Ram Murthy and Seetha Rama Rao, 2019](#)) The challenges arising from material design, cost-effective processing, characterization and matrix-reinforcement interfacial characteristics have been systematically addressed for the family of metal matrix composites [MMCs] by several researchers in their independent studies in the time period spanning the last four decades [1980–2020]. Sustained research and development efforts did eventually result in the development and emergence of particulate-reinforced metal matrix composites (MMCs) as potentially viable and an economically affordable option for the purpose of selection and use in a spectrum of applications spanning the fields of military, aerospace, electronics, ground transportation, infrastructure-related industry and high-performance end products. ([Miracle, 2005](#); [Gurusamy et al., 2015](#); [Hassan and Gupta, 2007](#)) Noticeable advances in the domains specific to compositional design commensurate with application have been made possible through sustained research and development efforts.

The ability of relatively inexpensive reinforcements coupled with advances and emergence of processing and fabrication techniques that can result in reproducible microstructures that offer consistent properties spanning the domains of mechanical, physical, electrical and chemical has engineered considerable scientific and technological interest in the selection and use of metal matrix composites (MMCs) for a wide spectrum of applications in the industries spanning automotive, aerospace and few structural end products. The need for reduced structural weight for both aerospace-related applications and automotive applications can be achieved by either increasing the elastic modulus of the engineered composite or by reducing density of the matrix and thus the resultant composite. [Degischer et al. \(1996\)](#) However, the resultant metal matrix composites (MMCs) tend to offer a few observable disadvantages when compared one-on-one with the monolithic counterpart, i.e., pure metal, to include the huge cost arising from processing, inadequate experience, coupled with an overall intrinsically complex processing and fabrication technique(s).

Fig. 1 Classification of metal matrix composites.

The properties to include specific strength (σ/ρ), elastic modulus, rigidity, corrosion resistance, wear resistance and thermal conductivity (Zhang *et al.*, 1993; Sastry *et al.*, 2001) have been noticeably enhanced by the engineering, or synthesis, of metal matrix composites [MMCs] that essentially comprises of a pure metal matrix, or an alloy, that is reinforced with ceramic, organic or metallic compounds. In the synthesis and fabrication of metal-matrix composites [MMCs], spanning both the aluminum-based (Al) composite and magnesium-based (Mg) composite have been given the highest priority when compared to other metals to include titanium (Ti), copper (Cu), nickel (Ni) and iron (Fe). The most prominent characteristics offered by the aluminum-based and magnesium-based metal matrix composites did gain noticeable attention when compared one-on-one with the other alloy-based composites. (Bhoi *et al.*, 2020; Samal *et al.*, 2020; Tjong and Ma, 2000; Gupta and Wong, 2015) Besides, preferential selection and use of the metal-matrix composites [MMCs] in the automotive industry was gradually reduced due essentially because of its low ductility, inadequate fracture toughness, inferior fracture resistance coupled with inferior corrosion resistance upon exposure to environments spanning a range of aggressiveness.

The characteristics specific to high performance and light weight did make the alloys of aluminum and magnesium to be chosen for use as the matrix material in developing composites for a spectrum of applications spanning the industries of automobile and aerospace. Macke *et al.* (2014) The most significant properties, such as good resistance to corrosion and good resistance to wear coupled with low density, high specific strength (σ/ρ) and high specific stiffness (E/ρ) were often exhibited by both monolithic aluminum and magnesium and their alloy counterparts. By systematically varying the size, nature and volume fraction of the reinforcing phase, it was possible to obtain the desired combination of properties for a specific application. Since then both aluminum-based MMCs and magnesium-based MMCs have been preferentially chosen and used for the manufacturing of both aerospace components and automobile components. In the aerospace industry the composites have been chosen for use in fuselage and wings while in the automobile industry the engineered metal-matrix composites have been preferentially chosen for disks, brakes, drums, and pistons. In several cases, the pure metal was often replaced by the alloy counterpart for the metal matrix.

The viable options for producing metal matrix composites [MMCs] were the following techniques: (1) stir casting, (2) mechanical alloying, and (3) powder metallurgy. (Kala *et al.*, 2014; Jayalakshmi *et al.*, 2013). The reinforcing particles often tend to undergo clustering or aggregation, poor interfacial interactions between the soft and ductile metal matrix and the hard and brittle reinforcement coupled with complex manufacturing-related problems that often occur during the conventional manufacturing processes used for the synthesis of the desired metal-matrix composite [MMC]. This often results in reduced, or degraded, mechanical performance of the as-synthesized metal-matrix composite (MMC). (Li *et al.*, 2016; Azamiya *et al.*, 2015) In an attempt to overcome problems specific and related to processing, the technique of spray processing has often been chosen and used as a potentially viable and attractive method for the synthesis of metal matrix composites [MMCs]. The two external powder injectors placed around the melt atomizing section aids in placing the reinforcing particles well within the spray cone during processing. Both clustering and aggregation of the reinforcing particles can be successfully prevented with the help of rapid solidification of the atomized droplets. Ye and Liu (2004).

To eliminate several of these problems and to concurrently increase the ability of a metal matrix composite [MMC] to be synthesized with ease a two-phase process is chosen. This includes the techniques of: (1) spray atomization and deposition processing, and (2) rheocasting. The objective of this article is to examine the key factors that affect and/or exert an influence on two-phase processing, resultant microstructure of the as-synthesized composite and the conjoint influence of processing and microstructure on mechanical behavior of both the aluminum-based composite and the magnesium-based metal matrix composite.

Manufacturing of Metal Matrix Composites

Final properties of the as-synthesized metal matrix composites [MMCs] are often decided and/or dictated by the processing technique that is chosen and used for the specific composite. Olszówka-Myalska *et al.* (2001) For a comprehensive evaluation of the MMCs, a few techniques have been researched upon and progressively developed during the past few decades [i.e., 1980-present] very much in conformance with the prevailing trend. The processing techniques were subsequently classified based entirely on temperature of the metal matrix during processing. Kandpal *et al.* (2014) The processing and resultant fabrication of metal-matrix composites [MMCs] at both the experimental stage and industrial or commercial stage can be broadly classified into the following five stages:

- (1) Liquid phase processes.
- (2) Solid phase processes.
- (3) Deposition techniques.
- (4) In situ processes, and
- (5) Two phase (solid-liquid) processes.

In liquid phase processing, through the use of different proprietary methods the reinforcing particles are gradually added to the molten metal matrix, and the resultant mixture is then allowed to undergo gradual mixing. This culminates with the resultant composite mixture being gradually poured to get components having a definite shape or billets. The billets are subjected to subsequent fabrication with the purpose of getting the desired end product. The techniques of squeeze casting, spray decomposition processing, and liquid metal infiltration, are the three most widely preferred and used liquid phase processing techniques.

In solid phase processing, the blended mixture of elemental powders and reinforcing particulates results in the development of particulate-reinforced metal matrix composite [MMC]. Prior to final consolidation of the blended mixture, few to several measures are often taken to ensure overall success of this processing technique. The techniques of (1) high energy high rate forming, (2) diffusion bonding, and (3) powder metallurgy are categorized to be solid phase processing techniques.

In the manufacturing of metal-matrix composites [MMCs] by use of the technique of spray deposition processing often necessitates the need for the reinforcement fillers to be placed within the matrix material, which results in formation of the desired composite. Subsequently, diffusion bonding of the reinforcement with the metal matrix results in a consolidated composite that conforms with the structural shape that is desired. The techniques of: (1) immersion plating, (2) electro-plating, (3) spray forming, and (4) spray decomposition, are some of the widely chosen and used decomposition processes. The technique of in-situ processing is also referred to as reactive processing. In this processing technique, refractory reinforcements are favored to form in an aluminum alloy metal matrix by reaction.

A combination of the hard, brittle and elastically deforming ceramic reinforcement with a soft, ductile and plastically deforming metal matrix was carried out in two-phase processes in the area of the phase diagram where the matrix contains both the liquid phase and the solid phase. Based on this two-phase processing concept, the following three techniques were found to be technically viable and economically affordable and hence the most prominent:

- (1) Spray atomization and deposition.
- (2) Rheocasting.
- (3) Osprey deposition.

Spray Atomization and Deposition Processing

The spray atomization and deposition processing is a semi-liquid synthesis technique that has been preferentially used for the purposes of processing discontinuously-reinforced metal-matrix composite [MMC]. In this specific technique, the metal matrix in the semi-solid state and the desired reinforcement are thoroughly mixed. This processing technique offers several unique properties that vary from solid to liquid and two-phase processing. In this technique, both mixing and consolidation are finished in a single operation, which is by far the most important and key aspect specific to this technique.

The atomizing of matrix material into a fine diffusion of droplets using pressure-controlled inert gas jets that also aids in heating the reinforcing particles during flow through the inlets is shown in Fig. 2. Garg *et al.* (2019).

Srivatsan and Lavernia (1992) have studied and documented the different synthesis techniques using particulate technology and came to the conclusion that the technique of spray deposition processing was one that was potentially viable, economically affordable and an overall attractive manufacturing technique for the production of high quality metal matrix composites [MMCs].

On a chosen surface the reinforcement can be applied upon which the molten metal is then sprayed. By introducing the particulate reinforcement into the metal spray and the resultant mixture is then co-deposited onto the surfaces. Thus, an ingot of the desired metal-matrix composite [MMC] can be produced using the technique of spray deposition processing. A uniform supply of the reinforcing particulates by ensuring careful control of both the atomizing and reinforcement feeding conditions is essential. A few of the manufacturing techniques coupled with essential mechanical property characterization of the as-synthesized MMC was initially studied and put forth by Mistry and Gohil (2017). They came to the conclusion that spray deposition processing did offer a useful

Fig. 2 Spray atomization and deposition of metal-matrix composites. Reproduced from Mistry, J.M., Gohil, P.P., 2017. Research review of diversified reinforcement on aluminium metal matrix composites: Fabrication processes and mechanical characterization. *Science and Engineering of Composite Materials* 25 (4), 1–15.

combination of high production rate and low solidification time. This is particularly advantageous for the synthesis of a metal-matrix composite [MMC] by enabling minimum reaction time of the chosen matrix material with the particulate reinforcement.

Rheocasting Process

In the technique of rheocasting, (Arunachalam *et al.*, 2019) a semi solid slurry is developed from the molten alloy through shearing action and the reinforcement particles are often trapped during the solidification process. To ensure shaping of the desired component, the resultant slurry is often transferred to a die. The key aspects specific to the technique of rheocasting are the following: (1) in-house scrap, (2) energy saving recycling, and (3) feed stock like special solid billet, which is often required for the technique of thixocasting. Due to a healthy combination of overall cost effectiveness coupled with high productivity for manufacturing of the semi-solid metal (SSM), (Elsharkawi *et al.*, 2014) this processing technique has stood out to be the most prominent fabrication technique during recent years. By applying pressure on the chosen reinforcement often results in an excellent microstructure coupled with highly localized intensive shearing that contributes in an observable way to enhancing distribution of the reinforcing particles in the chosen metal matrix of the as-synthesized metal-matrix composite [MMC]. Ostad Shabani *et al.* (2016) By a careful addition of the reinforcing particles to the partially solid alloy, it is possible to prevent both the settling and agglomeration of the reinforcing particles by this technique.

The reinforcement should not only be constant at a specific temperature but also non-reactive during the entire rheocasting process. Silicon carbide (SiC) and aluminum oxide (Al_2O_3) were the two most common reinforcements that have been chosen for reinforcing metal matrices. A systematic diagram of this process is shown in Fig. 3. Curle and Ivanchev (2010) The primary advantages of this technique are a high-quality cast component of the as-processed, or as-synthesized, metal matrix composite, to include the following:

- (1) Free of porosity,
- (2) Complex parts,
- (3) Excellent filling of the metal,
- (4) Acceptable mechanical performance,
- (5) Reduced shrinkage, and
- (6) Good surface finish.

When compared one-on-one with the other methods of casting, the wear property of the Rheosqueeze cast metal matrix composite [MMC] is noticeably evident. The primary disadvantage with this technique is that it necessitates the need for advanced technology for the purpose of production, which requires that the desired operators be both aware and knowledgeable of the intricacies specific to advanced technology while concurrently exposing themselves to adequate training. Very little work has been done with this processing technique and up until now no effective and extensive materials characterization data can be found in the published literature. (Flemings *et al.*, 1976; Poddar *et al.*, 2009; Rahimi *et al.*, 2015).

Curie *et al.* (Curle and Ivanchev, 2010) manufactured silicon carbide reinforced cast aluminum alloy AA359-based composites using the technique of rheocast processing. They observed the hardness of the as-synthesized composite to increase from 73 HRB to 93 HRB for an increase in silicon carbide (SiC) reinforcement content by as much as 11 vol%.

Fig. 3 Schematic showing apparatus for the Rheocasting of metal matrix composites. Reproduced from Arunachalam, R., Krishnan, P.K., Muraliraja, R., 2019. A review on the production of metal matrix composites through stir casting – Furnace design, properties, challenges, and research opportunities. *Journal of Manufacturing Processes* 42, 213–245.

Fig. 4 A schematic of the modified Osprey technique.

The Osprey Deposition Process

In the Osprey deposition process, the reinforcing particulates are in touch with the molten alloy and the resultant mixture is carefully atomized using inert gas jets during synthesis of the metal-matrix composite. [Leatham et al. \(1990\)](#) This is shown in [Fig. 4](#).

In the form of reinforced metal matrix billets, the final sprayed mixture is collected on the surface. The Canadian aluminum company [ALCAN] was the first to introduce this method as an extrapolation of the Osprey process. [White et al. \(1988\)](#) This processing technique was essentially a combination of both blending and consolidation steps specific to the powder metallurgy process. This has made possible observable strides in the synthesis, development and emergence of metal-matrix composites [MMCs].

The Osprey deposition is a typical two-phase processing technique that has found for itself selection and use for both high performance-critical and low performance-critical applications. Through the spray jets of inert gas, the reinforcing particulates are injected and atomized to the substrate of the molten-metal or alloy matrix. The resultant solid mixture is then held onto a non-wetting surface. Recent studies have convincingly shown that the spray atomized products are essentially free of microscopic segregation while concurrently possessing fewer gas content. Besides, they are capable of having certain characteristics, which can be related to rapid solidification processing. Extruded billets of an aluminum-silicon alloy ([Ejiofor and Reddy, 1997](#)) having noticeably good to outstanding dimensional tolerance have been easily fabricated using the technique of Osprey deposition.

Properties of Metal Matrix Composites [MMCs] Produced Using Various Two-Phase Processes

A proper selection of the variables to include the following: (1) reinforcement, (2) processing technique chosen, (3) parameters specific to the processing technique, and (4) matrix of the as-synthesized metal matrix composite [MMC] does help in engineering improvements in the overall quality of the engineered metal-matrix composite [MMC]. The parameter can in fact either be modified or tailored to suit a particular application.

[Chaorun et al. \(Si et al., 2017\)](#) produced silicon carbide particulate [SiC_p] reinforced aluminum alloy 7075-based composites using the technique of spray atomization and deposition processing. In an attempt to evaluate the proposed technique, the microstructure and mechanical behavior of test specimens of the as-synthesized composite were compared one-on-one with the conventional spray formed aluminum alloy 7055. Microstructure of the as-synthesized aluminum alloy 7055 - SiC_p metal-matrix composite [MMC] had near equiaxed shaped grains with an overall fine structure. This is evident in the optical micrographs shown in [Fig. 5\(a\)](#). As seen in [Fig. 5\(b\)](#), under identical atomizing conditions the microstructure of the as-synthesized aluminum alloy 7055/SiC_p composite had grains with an average size of 16 μm, which was noticeably smaller than that of the spray formed aluminum alloy 7055 counter-part (about 24 μm).

An observable improvement in mechanical properties of the spray formed or spray processed composite, i.e., MMC, due to the refined grain size, has been both observed and recorded in an earlier study. [Liu et al. \(2016\)](#) A schematic of the spray deposition processing technique along with optical micrographs of the as-synthesized aluminum alloy based metal matrix composite are shown in [Fig. 6](#).

The XRD curves and the strain versus stress response in compression for the 7055-SiC_p composite and the unreinforced counterpart, i.e., aluminum alloy 7055, at room temperature [27°C], are shown in [Fig. 7](#). The second precipitate phase that was present in the microstructure was the η phase (MgZn₂). This is evident for the 7055-SiC_p composite from the X-ray diffraction (XRD) curves shown in [Fig. 7\(b\)](#). A nominal increase of 4.64% for the compression peak strength i.e., 687.5 MPa, was observed for the 7055-SiC_p composite when compared one-on-one with the spray formed aluminum alloy 7055. This is clearly shown in [Fig. 7\(a\)](#). Further, this provides convincing evidence for two-phase atomization and deposition processing to be safely considered as one of the most prominent processing techniques proposed for the family of metal matrix composites [MMCs].

Fig. 5 Optical micrographs showing grain structure of (a) 7055-SiCp composites, and (b) Spray formed 7055Al alloy.

Fig. 6 (a) A schematic of the spray deposition process. (b) Optical micrographs showing microstructure of the as-synthesized 7055-SiCp composite, and (c) High magnification observation of (b).

The observed enhancement in mechanical properties of the as-synthesized 7055/SiCp composite when compared one-on-one with the spray formed 7055 aluminum alloy counterpart can be attributed to the conjoint and mutually interactive influences of the following:

- (1) A decrease in grain size of the 7055 SiCp composite as a direct consequence of atomization resulting in fine grain strengthening.
- (2) A near uniform distribution of the reinforcing silicon carbide (SiC) particles through the aluminum alloy metal matrix that ensures noticeable contribution from particle strengthening.
- (3) During phase atomization and deposition processing a rapid solidification of the alloying elements does result in a super saturated solid solution (SSSS) and the resultant strengthening from the solid solution.

Yang *et al.* (2019) did conduct an exhaustive study of the Al7055/SiC_p composites using the technique of spray deposition. The volume fraction of the reinforcing silicon carbide particles (SiC_p) in the aluminum alloy metal matrix was 17%. The effect of SiC_p on both microstructural development and resultant mechanical properties of the as-synthesized composite was carefully examined. In this independent study, the spray-deposited AA7055/SiC_p metal matrix composite was composed of alpha-aluminum, silicon carbide particulates (SiC_p), and the precipitates Al₂CuMg, Al₂Cu and MgZn₂. Size of the liquid particles of aluminum are noticeably different, and the phenomenon of large particles consuming the small particles was common in areas containing a high volume fraction of the reinforcing SiC particles. This is essentially because of a synchronization of the nucleation kinetics caused by noticeable differences in cooling rates of the hard and brittle reinforcing SiC particles and the soft and ductile aluminum alloy

Fig. 7 (a) Stress-strain curves and X-ray diffraction patterns (XRD) for both the aluminum alloy 7055-SiCp composite and aluminum alloy 7055. (b) X-ray diffraction patterns of the as-synthesized 7055-SiCp composite and the unreinforced aluminum alloy 7055.

metal matrix. The silicon and carbon present on the surface of the reinforcing SiC_p tend to gradually diffuse into the aluminum metal matrix. A distribution of these two key elements, i.e., carbon and silicon, followed by a pattern of gradual weakening of the reinforcing SiC particles (SiC_p) results in the formation of a ring-shaped zone that is enriched in both carbon and silicon around the reinforcing SiC particles. The presence of two phases, i.e., AlCu and AlMgCu, in the as-synthesized composite was detected both at and along the boundaries of the liquid aluminum particle, but also on the surface of the reinforcing silicon carbide (SiC) particles. These particles or phases tend to gradually grow both at and along the edges and corners of the reinforcing SiC_p. The reinforcing silicon carbide (SiC) particles tend to hinder or prevent propagation of both the tear edges and fine microscopic cracks. The tear edges and fine microscopic cracks will tend to gradually propagate around the reinforcing SiC particles (SiC_p). This contributes in a small way to increasing their propagation path while concurrently contributing to delaying failure of the material by fracture. Conventionally, a high temperature is maintained during the deposition processes. Subsequent to atomization, droplets of aluminum alloy 7055 will tend to react with the reinforcing silicon carbide particles (SiC_p). The gradient region of silicon and carbon was gradually dissolved from surface of the reinforcing SiC particle (SiC_p). This can be seen from the EDS midline scanning that is shown in Fig. 8.

Mechanical properties of the aluminum alloy metal-matrix composites in the radial direction were found to be better than those in the longitudinal direction. The tensile strength and elongation following fracture was 17.4% and 8% higher in the radial direction when compared to the longitudinal direction. Fracture morphology of the chosen aluminum alloy based metal matrix composite essentially revealed a combination of cleavage and pockets of dimples, with few features reminiscent of “locally” brittle fracture.

Esmaily *et al.* (2016) fabricated SiC particle-reinforced AM50 matrix composite and AZ91D matrix composite using the technique of RheoMetal process by investigating the newly developed and emerging technique of rheocasting (RC). The microstructure and hardness of the as-synthesized magnesium-based metal matrix composites [MMCs] was examined and compared one-on-one with the unreinforced counterpart.

In this study, the researchers used two separate experiments to examine the effect of rheocasting process on microstructure of the rheocast magnesium alloy AM50-based MMC and AZ91D-based MMC. In the first experiment, they fabricated SiC particle-reinforced magnesium-based MMCs to examine the formation, presence and distribution of the different intermetallic particles through the microstructure during solidification. In the second experiment, by quantitatively analysing the microstructure of the as-synthesized metal-matrix composites (MMCs), they were able to systematically investigate the magnesium alloy-based MMCs for different volume fractions of the particulate reinforcement. They found the reinforcing SiC particles to be distributed uniformly through the microstructure. Use of image analysis technique helped in differentiating the parent alloy with specific reference to both defects created during casting and the resultant microstructure.

The fabrication of rheocast AZ91-based and rheocast AZ50-based MMC is shown in Fig. 9. The molten metal was converted into slurry using internal enthalpy exchange material (EEM) that is needed for the Rheocast process.

The resultant metal matrix composite (MMC) was fabricated from the RheoMetal that was placed between two liquid metals at a comparatively low super heat and the solid metal attached to a stirrer. The rod tends to cool to a normal temperature upon immersion in the melt. In this method, the melt was cooled noticeably faster than melting of the enthalpy exchange material (EEM) and a homogeneous slurry was ensured during processing. The two magnesium alloys that were chosen as matrices were:

Fig. 8 (a) The line scanning image, and (b) Distribution of the elements carbon (C) and silicon (S) along the scan line in (a) of spray-deposited AA7055/SiCp metal matrix composites.

Fig. 9 A schematic of the rheocast (RC) process used for the fabrication of magnesium-alloy based metal matrix composites.

Fig. 10 X-ray diffraction (XRD) diffractograms of RC AM50 and AZ91D reinforced with silicon carbide (SiC) particles.

(1) AM50, and (2) AZ91D. Further, two different sizes of the reinforcing SiC particles (SiC_p) were used for the purpose of manufacture of the desired metal matrix composite. The first experiment involved reinforcing the SiC particles (SiC_p), ranging in size from 0.1 μm to 0.9 μm (HCS 59N), with magnesium alloy AZ91D. In the second experiment for magnesium alloy AM50 the reinforcing SiC particles (SiC_p) varied in size from 4 to 28 μm (HCS 400).

The X-ray diffraction patterns for the rheocast AZ91 MMC and rheocast AM50-based MMC are shown in **Fig. 10**. With specific reference to α -Mg, the β -phase ($\text{Mg}_{17}\text{Al}_{12}$) had a comparatively low intensity peak for the two chosen composites. These peaks could be easily detected for the AZ91D alloy while it was difficult to detect for the AM50 alloy. The β -SiC had strong peaks for the two chosen magnesium alloys. When compared to magnesium alloy AZ91D, the peaks related to the intermetallic particles MgO and Mg_2Si had better, clear and sharp intensity.

For both the magnesium alloy-based metal matrix composites [MMCs], a few of the peaks had properties that were similar to magnesium Hydride (MgH_2).

The microstructure of magnesium alloy AM50 and magnesium alloy AZ91D reinforced with SiC particles (HCS 59N) is as shown in **Fig. 11**. The SiC particulate clusters were seen in both the AM50 alloy and AZ91D alloy, which can be inferred from the scanning electron microscopy images. A few noticeable changes in the grain structure was observed for the SiC particle reinforced AM50-based metal matrix composite [MMC].

For the AM50 alloy-based composite, an observable decrease in the grain size of α -Mg, by as much as 28-mm, was observed. Furthermore, an increase in aspect ratio of ~ 0.8 was observed for the α -Mg grains that was made possible by the addition of the reinforcing SiC particles. This clearly demonstrates a noticeable enhancement in the spherical morphology of the primary α -Mg grains. In the inter dendritic regions traces of the β -phase particles were observed. Similar observations were recorded for the AZ91D alloy-based MMC.

The intrinsic difference in hardness of the alloys AM50, AZ91D, and the composite counterparts is shown in **Fig. 12**. It is observed that the engineered MMCs were noticeably harder than the host alloy. Due to the presence of clusters of the reinforcing SiC particulate (SiC_p) in the as-synthesized MMCs an observable difference in the hardness values was noted. The hardness value of alloy AM50 and alloy AZ91D were increased to a maximum value in the range of ~ 50 to 73 and ~ 64 to 76 with the use of HCS 59N particulate reinforcement. The HCS 400 particulate reinforcement revealed lower hardness than HCS 59N, which incidentally is noticeably harder than the unreinforced rheocast alloys AM50 and AZ91D.

Poddar *et al.* (2009) studied the mechanical properties and microstructure characteristics of SiC particle- reinforced magnesium-based composite synthesized using the technique of rheocasting. A temperature of 596°C and 468°C was applied to both the liquidus and solidus states in this independent research study. The magnesium ingot pieces were placed in a mild steel crucible that was coated with boron nitride kept in a resistance furnace during the initial stages. Prior to charging the crucible, the raw materials were preheated at 250°C. The furnace temperature was then increased to 750°C for 30 min. At this temperature the melt was kept for the purpose of ensuring complete homogenization. During stirring, the preheated SiC particles (SiC_p) were gradually added to the alloy slurry. Using a rotational speed of 450 rpm and maintaining a temperature of $584 \pm 2^\circ\text{C}$, the melt was gradually stirred with the help of a mechanical stirrer for full 20 min during the rheocasting process. Subsequently, the slurry was filled into rectangular molds that measured 20 mm $\times$ 100 mm $\times$ 300 mm. The resultant ingots of both the rheocast alloy and the composite counterpart were heat treated at a temperature of 415°C for 18 h in an environment of carbon dioxide gas.

These researchers also reported the SiC particles (SiC_p) to be uniformly distributed in the matrix of the rheocast AZ91D alloy. The fine size of the reinforcing SiC particles did result in their agglomeration in the as-synthesized AZ91D/15 SiC_p composite. The growth of primary α -Mg grains forced the reinforcing particles to the grain boundary regions and their small size was conducive for both clustering and agglomeration. The clustering and agglomeration of the reinforcing SiC particles at the boundary regions was essentially because of the high surface tension force due to the high volume ratio at the region of the interface.

The values of hardness of the as-cast composites are summarized in **Table 1**. When compared to the unreinforced counterpart, the composite samples did possess noticeably higher hardness. The hard and brittle reinforcing SiC particles (SiC_p) tend to suppress matrix

Fig. 11 Scanning electron micrographs of rheocast magnesium-based MMC, (a) and (b) AM50 alloy-based metal-matrix composite (MMC), (c) and (d) AZ91 alloy-based metal matrix composite (MMC).

Fig. 12 Hardness of Rheocast alloys and the resultant metal matrix composites [MMCs].

Table 1 Results of hardness measurement on both the As-cast and T4 heat-treated specimens

Material	Condition	Particle size (μm)	Microhardness (HV, 0.5 N)	
			Matrix (± 1)	SiC/matrix interface (± 3)
AZ91D	As cast	–	62	–
AZ91D	T4	–	75	118
AZ91D/15 SiCp	As cast	150	78	106
AZ91D/15 SiCp	T4	150	65	–
AZ91D/15 SiCp	As cast	15	77	93
AZ91D/15 SiCp	T4	15	81	89

deformation by constraining the movement of dislocations. The load bearing capacity of the resultant composite material was enhanced by the presence of the reinforcing silicon carbide particles (SiC_p)s in the microstructure of the engineered composite material. At the particle-matrix interfaces, the micro-hardness value revealed an observable decrease following the T4 heat treatment.

The total elongation for the AZ91D/15 SiC_p (grain size of 150 μm) composite was 1.6% and for the AZ91D/15 SiC_p composite (grain size of 15 μm) it was 1.8%, which is noticeably less than that for the unreinforced alloy (8%). The gradual transfer of load from the soft, ductile and plastically deforming metal matrix to the hard, brittle and essentially elastically deforming particulate reinforcement was the basic mechanism governing deformation of the chosen composite at the fine microscopic level. Enhanced mechanical properties coupled with good load carrying capability could be easily achieved by the good bonding between the reinforcing silicon carbide particles (SiC_p) and the chosen metal matrix.

The Osprey process was developed to prepare both aluminum-based and aluminum alloy based metal matrix composites. [Leatham et al. \(1989\)](#) In this technique, the reinforcement particle was introduced into a stream of the molten alloy. The molten metal is subsequently atomized using a jet of inert gas. The sprayed mixture was allowed to solidify on a substrate resulting in the formation of fine pellets.

A method for manufacturing hypereutectic Al-Si alloys was developed by Osprey Metals Ltd, which was termed as the Osprey deposition process and was based essentially on the technique of spray deposition. The need for both a simple technique and low processing cost was essential since the processing parameters were often complex and the resultant manufacturing cost was noticeably high. An important aspect was the critical need to maintain flow rate of the melt along with the required characteristics for both atomization and deposition. [Cai et al. \(2015\)](#).

Conclusions

This article provides an adequate insight into the two-phase fabrication process coupled with a brief overview of both microstructure and mechanical characteristics of the as-synthesized metal matrix composites [MMCs]. The advantages and limitations of each of the processes are presented and briefly discussed. Choice of the appropriate processing technique is influenced by a variety of factors to include: (1) production cost, (2) process efficiency, (3) quality desired in the product, and (4) end application. A few of the key highlights resulting from this short article are the following:

- (1) Of the several methods for fabrication, spray deposition has now gained the recognition of being the most promising technique for the purpose of development of metal-matrix composites [MMCs] due to a healthy synergism of a technically viable and an economically affordable cost-effective process.
- (2) The metal matrix composites [MMCs] having improved mechanical properties can be successfully produced by an appropriate selection of the processing technique and the associated process parameters to include the following: (1) nature of the metal matrix, (2) type, nature and volume fraction of the reinforcing phase, (3) other additives used, if any, and (4) use of wetting agent.
- (3) The extensive macroscopic segregation that is normally associated with traditional casting processes can be either prevented or minimized by the technique of Spray Atomization and Deposition processing.
- (4) Test samples of the rheocast Mg-SiC composites revealed noticeable improvement in elastic modulus, hardness and yield strength, with a marginal decrease in ductility and ultimate tensile strength.
- (5) Aluminum alloy 7075, which is a preferred candidate for selection and use in structural applications in combination with silicon carbide (SiC) reinforcement finds for itself selection and use in industries spanning the automobile sector and performance-related products.

Additive Manufacturing of Metal Matrix Composites

Sankaranarayanan Seetharaman and Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introduction

Metal matrix composites comprise of a continuous metallic matrix dispersed with hard and strong reinforcement phases typically in the forms of fibers or particles. They exhibit excellent combination of properties like improved strength, elastic modulus and damping characteristics, superior wear resistance, and reduced thermal expansion which are highly suitable for automotive, aerospace, space, defense, sports, electronics and tooling applications.

While MMCs made of Al, Ti, and Mg alloys are commonly recommended for structural lightweighting, Ni based MMCs find applications as high temperature materials. Similarly, Fe and Cu based MMCs are widely used in tooling and electronic packaging industries, respectively. In case of reinforcements, study of available literature highlights the extensive use of Al_2O_3 , SiC, TiC, B_4C in the form of discontinuous particle reinforcements. However, fibers and whiskers made of graphite, SiC and Al_2O_3 are also used for demanding engineering applications (Kainer, 2006).

Traditionally, MMCs are produced using stir casting, melt infiltration, deposition, powder metallurgy and mechanical alloying methods which can be grouped under liquid and solid-state processing methods as shown in Fig. 1.

Each of the above-mentioned conventional methods has their own set of benefits and limitations and the same has been extensively reported in open literature. Recently, MMCs based on Al, Ti, Fe and Ni alloys with superior mechanical properties are also produced using additive manufacturing methods. Additive manufacturing (AM) refer to layer by layer joining of powder to make end-usable products. The benefits of AM over traditional manufacturing include: (1) complex part manufacturing without excess tooling needs, (2) reduced number of processing steps and (3) minimal requirement for post-processing (Gibson *et al.*, 2010b).

The commercial AM processes are broadly classified into three main groups: (1) liquid-based systems, (2) solid-based systems and (3) powder-based systems (Gibson *et al.*, 2010a). While the liquid-based systems are effective for polymer processing, powder and solid-based systems can be utilized for fabricating metallic materials. While all these methods involve a layer-based manufacturing approach starting from the CAD model generation to post-processing/finishing of built parts, they essentially differ by means of: (1) materials that can be used and their initial properties, (2) how the layers are created, and (3) how the layers are bonded to each other. Such differences will eventually determine the accuracy of build part, its properties and performance.

Solid-Based Systems

Material extrusion, ultrasonic consolidation (UC) and electron beam additive manufacturing (EBAM) processes use solid raw material to produce three-dimensional solid objects (Domack and Baughman, 2005; Antonysamy, 2012). While the FDM process commercialized by Stratasys is very popular for making polymer 3D parts through the extrusion of thermoplastic material from a nozzle, metal extrusion is relatively new in which the filament for extrusion is a combination of thermoplastic material and metallic particles (3DEO, 2018). In metal extrusion, the printed parts are compulsorily subjected to post-processing heat treatment process in order to burn out the plastic remains and for better consolidation.

UC patented by Solidica and Sciaky's EBAM techniques can be employed for metallic parts fabrication (Domack and Baughman, 2005; Antonysamy, 2012). UC process produce complex part geometries by sequentially laminating the metal foil layers using an ultrasonic sonotrode to induce vibrations for joining/welding. Unlike other additive technologies wherein the bonding between layers is generated by selective heating/melting of powder materials, UC applies ultrasonic joining technique to produce true metallurgical bonds between layers of metallic materials. This method can be successfully used to manufacture low melting point metal parts with following advantages: (1) higher fabrication speed, (2) no requirement of control atmosphere, and (3) reduced residual stresses and part distortion.

EBAM uses wire feed raw material for fabricating metallic materials. This method promises high deposition rates and ability to fabricate large part sizes. A similar electron beam based free-form fabrication (EBF3) method has been used by NASA to build parts in zero gravity environments.

Powder Based Systems

Nowadays, powder-based AM systems based on laser and electron beam source attract extensive interest in metallic part fabrication. Fig. 2 shows the family tree and basic working principle of different powder bed AM systems.

Binder Jetting involves layer by layer spreading of powder materials which were subsequently joined by selectively applying glue using an inkjet head. The major advantage of this method is that it can be applied for joining metal powders. The major limitation of this process is that it always requires post processing steps such as oven sintering, isostatic pressing etc., as the final product fabricated using this process is not very strong.

Crack and wear behavior of SiC particulate reinforced aluminium based metal matrix composite fabricated by direct metal laser sintering process. *Materials and Design* 32. Available at: <https://doi.org/10.1016/j.matdes.2010.06.020>.

Laser sintering (LS) process was first developed at the University of Texas. This process involves layer by layer spreading of powder and subsequent sintering using a low power (CO₂) laser source. The general processing procedure includes a roller to deposit a fine layer of powder on the build platform. The laser source (typically 50 W) will then selectively sinter the powder and completes the fabrication of one layer. For the next layer, the powder bed is then lowered by one-layer thickness and the new layer of powder material is then deposited and sintered. This process is continued until the complete part is produced. As the power of the laser in the SLS machine is not enough to melt metals and ceramics, they are often coated with the polymer which acts as a binder. After sintering, the binder is removed (by burning) and then the mold is infiltrated with a low melting point metal or alloy.

Laser Melting (LM) is very similar to sintering process, except that a high power (fiber) laser source is used to selectively melt the uncoated metal powders melted to produce high-strength metallic parts. This method shows better suitability to produce full dense parts approaching 99.9% density in a direct way, without post-infiltration, sintering or hot isostatic pressing. Since the selective laser melting (SLM) process does not require burning out of polymer and post-densification, the time required for producing a metal part is reduced in SLM when compared to the SLS process. Another major advantage lies in its high feasibility in processing non-ferrous metals such as Ti, Al, Cu, which cannot be well processed using partial melting and associated high viscosity and balling phenomenon. However, the high energy level required for melting the powder materials and the risk of unstable melt pool resulting in large shrinkage and residual stress are regarded as key limitations. Currently, the LM machines are marketed by 3D systems, Concept laser, EOS, SLM, AddUp, Trumpf and Matsuura.

Electron Beam Melting (EBM) process developed at Chalmers University of Technology, Sweden and marketed by Arcam, works on the similar principle as selective laser melting except that the melting of powder materials was done using a focused electron beam emitted from a heated tungsten filament. The electron beam interacts with the metal powder on the platform so that the kinetic energy of the electron beam is converted to heat and melts the region of the metal powder. Since this process requires high vacuum for electron beam processing, better mechanical properties can be achieved by using EBM process. However, the EBM process has few limitations such as: (1) process stability, (2) part defects, (3) quality variations, and (4) size of building chamber.

Laser Deposition (LD) methods involve localized melting and deposition of powder materials using a high-power laser source. The carrier medium which is usually an inert gas feeds the powder through nozzles. Upon interaction with laser, the powder melts and the molten material is deposited on the platform based on the CAD data. This technology has been commercialized by POM, Optomec, Aeromet and MTS as direct metal deposition (DMD), laser engineered net shaping (LENS), laser rapid forming (DRF), laser cladding (LC), and laser additive manufacturing (LAM) respectively. The deposition methods can be effectively used to produce titanium alloys, nickel alloys, steels, cobalt alloys, aluminum alloys and composite coatings. Their advantages include: (1) production of fully dense materials with good metallurgical properties at reasonable speeds, (2) capability to build intricate features and shapes, (3) ability to integrate features to cast or forged parts for repair purposes. The major limitations are: (1) difficulty in building overhung parts and features, (2) microstructural control, (3) poor surface finish, and (iv) residual stress.

Although there have been only a limited number of commercial materials that can be used in AM processes, the aerospace, automotive and tooling industries are successful in adopting the additively manufactured metallic materials for applications in automobile brackets, gas turbines, heat exchangers, reactor vessels, conformal cooling etc. While the additive manufactured MMCs exhibit excellent properties that are comparable/superior to that of other conventional manufacturing methods, issues related to processing and properties such as residual porosity, cracks, mechanical anisotropy, residual stress and poor surface finish resulting from additive processing need better understanding on process-structure-property relationships. In this article, an attempt has been

Fig. 4 Compressive response and wear resistance of SLM processed Al-12Si-TNM composites reported by (Prashanth *et al.*). Reproduced from Prashanth, K.G., *et al.*, 2016. Processing of Al-12Si-TNM composites by selective laser melting and evaluation of compressive and wear properties. Journal of Materials Research 31. Available at: <https://doi.org/10.1557/jmr.2015.326>.

made to summarize the research progress made so far on the laser additive manufacturing of metal matrix composites based on aluminum, titanium, nickel, iron and copper alloys.

Additive Manufacturing of Aluminum Matrix Composites

Aluminum matrix composites (AMC) are widely recommended for the structural light weighting of automobiles. The additive manufacturing of AMC was first performed by Ghosh *et al.* (2010); Ghosh and Saha (2011) using a self-assembled primitive set up containing NDYAG laser source. In this work, the effects of particle size and volume fraction of SiC particle reinforcement were assessed in terms of the density, microstructure, hardness and wear resistance of the developed composites. While the use of 300 mesh size SiC particles imparted better density, improved hardness was achieved in the case of 1200 mesh size SiC reinforcement. The cracking susceptibility was found to increase significantly when the SiC content extended beyond 15 vol% SiC. The results also showed adverse effects on wear resistance with increasing reinforcement size and content beyond 20 vol% Figs. 3–10.

Al-12Si matrix reinforced with TNM (Ti52.4Al42.2Nb4.4Mo0.9B0.06, at%) particles were produced using selective laser melting by Prashanth *et al.* (2016). The reaction between TNM particles and the matrix produced Al_6MoTi intermetallic phases to improve the compressive strength and wear resistance of the composite Figs. 11–17.

In a similar study, 40 vol% TiB_2 reinforced Al-12Si coatings were prepared using the method of laser cladding (Anandkumar *et al.*, 2011). As expected, the developed AMC coatings exhibited better hardness ($156 \text{ HV}_{0.1}$) and superior wear resistance ($2.65 \times 10^{-5} \text{ mm}^3/\text{Nm}$) compared to monolithic alloy due to the microstructural composition containing primary α -Al-dendrites +

Fig. 5 Microstructure and mechanical properties of Al-12Si-40TiB₂ composite from (Anandkumar *et al.*). Reproduced from Anandkumar, R., Almeida, A., Vilar, R., 2011. Wear behavior of Al-12Si/TiB₂ coatings produced by laser cladding. Surface and Coatings Technology 205. Available at: <https://doi.org/10.1016/j.surfcoat.2011.01.048>.

inter-dendritic Al-Si eutectics and the uniformly distributed TiB₂ particles. Additionally, the results reported no reaction products contributing towards a clear interfacial load transfer to achieve a hardness of 156 Hv and lower wear rate **Figs. 18–23**.

Lorusso *et al.* (2016) also reported the improvement in wear resistance due to TiB₂ reinforcements. In this study, AlSi10Mg alloy and its composites reinforced with micro (10 wt%) and nano (1 vol%) sized TiB₂ particles were produced by direct metal laser sintering (DMLS) technique. The end properties of DMLS processed materials were also compared to that of the cast AlSi10Mg alloy **Tables 1–5**.

In a similar study, Chang *et al.* (2015) performed the selective laser melting of SiC/AlSi10Mg composite powder with different SiC particle size. Here the in-situ chemical reaction between SiC and AlSi10Mg resulted in hybrid (Al₄SiC + SiC) phases and the extent of in-situ reaction was found to enhance with increasing SiC content. The results showed at least 50% increase in micro-hardness and ~66% reduced wear rate for the composites.

Similar observations were also reported by Gu *et al.* (2015) and Zhao *et al.* (2019) where multiple phases like un-melted SiC, Al₄SiC₄, and eutectic SiC developed due to the in-situ chemical reaction. Similarly, the selective laser melting of Al₂O₃/AlSi10Mg composites powder produced in-situ produced Al₂Si₄O₁₀ phases reinforced AMCs (Jue and Gu, 2017). In case of Fe₂O₃ reinforcements, the in-situ chemical reaction produced α-Al₂O₃, Al-Fe intermetallics together with crystalline Si depending on the base matrix chemical composition (Dadbakhsh and Hao, 2014).

Aversa *et al.* (2017) prepared a composite blend of AlSi10Mg matrix containing micro or nanoscale TiB₂/MgAl₂O₄ reinforcements and used them to fabricate the respective bulk metallic composites using the method of DMLS. In this study, mechanical characterization results revealed lower yield and tensile strengths for all the composite formulations when compared to AlSi10Mg base alloy which was attributed to the relatively coarser microstructure of the composites developed due to the difference in volumetric energy density requirements.

A similar study reported the composite formation mechanism in SLM processed nano-TiC reinforced AlSi10Mg composite (Gu *et al.*, 2009). In this study, a higher densification was achieved only by optimizing the laser energy input per unit length at 700 J/m

Fig. 6 Properties of SLM processed hybrid ($Al_4SiC_4 + SiC$) reinforced Al Composites Modified from Chang, F., *et al.*, 2015. Selective laser melting of in-situ $Al_4SiC_4 + SiC$ hybrid reinforced Al matrix composites: Influence of starting SiC particle size. *Surface and Coatings Technology* 272, 15–24. and the insufficient energy inputs resulted in significant balling and porosity. This is because when the energy input is high, the larger melt pool and associated marangoni flow interacts with the solid particles to cause agglomeration/clustering. On the other hand, the lower intensity of thermocapillary flow and the shorted melt pool life prevents particle agglomeration at low energy

input. Hence, the dispersion of nano-scale reinforcement and composite densification strongly depends on the laser processing parameters.

In another recent study, Marchese *et al.* (2018) prepared a composite mixture of AlSi10Mg and nano-MgAl₂O₄ particles by dry mixing and ball-milling. The composite mixture was then processed using laser powder bed fusion technique with a combination of process parameters. While the end mechanical properties of the base alloy and the nanocomposite were largely influenced by the volumetric energy density inputs, the nanocomposite exhibited inferior properties post heat treatment.

Similar observations were also reported by Famodimu (2016) for SLM processed AlSi10Mg/SiC prepared using the ball-milled composite precursor. However, the properties were reported to be comparable to that of conventionally processed composites.

In a recent study, Li *et al.* (2017b) used a gas atomized composite precursor of nano-TiB₂ dispersed AlSi10Mg alloy for selective laser melting. The microstructure of composite developed in this study was significantly different when compared to those composites prepared by the laser melting of simply mixed or mechanical alloyed powder mixture. The use of gas atomized powder contributed towards better interface tailoring compared to particle agglomerates which are common otherwise. Also, a better strength was realized due to a finer microstructure with random crystallographic texture. This study highlighted the use of composite powder precursor for selective laser melting to produce dense and defect free AMCs with superior mechanical properties although the preprocessing is expensive when compared to mechanical alloying.

Recently several attempts have also been made to develop carbon nanotubes (CNT) reinforced AMCs using the method of selective laser melting (Zhao *et al.*, 2016; Wang *et al.*, 2017). While a finer microstructure and better strength of the composite were realized due to laser processing, the direct interaction with the laser source was found to decompose the CNTs.

Using the method of friction deposition, (Karthik *et al.*, 2017) fabricated a metal-metal composite consisting of AA5083 alloy matrix containing 12 vol% nanocrystalline CoCrFeNi high-entropy alloy reinforcement particles. In this study, the inert nature of high entropy alloy reinforcement contributed towards a clear layer-to-layer and reinforcement/matrix interfaces. Also, the

composite showed better tensile and compressive strengths and ductility than the conventionally processed wrought alloy and composite counterparts.

Additive Manufacturing of Titanium Matrix Composites (TMCs)

Recently there has been a focused attention on the additive manufacturing of TMCs for applications in aircraft engines and structures. However, the additive processing poses some serious challenges in densification due to significantly different densities, viscosities and melting/solidification behaviors between the matrix and reinforcements, unavailability of composite feedstock, and oxidation issues during powder processing etc. Hence an attempt has been made in this section to summarize the progress on additive manufacturing of titanium matrix composites with respect to the critical aspects such as processing, microstructure, mechanical and tribological properties.

Liu and DuPont (2003) employed the LENS process to produce TiC reinforced functionally graded Ti-composites in which the TiC particles content was varied upto 95 vol% without any cracking issues. In a similar study (Zhang *et al.*, 2008), the increasing TiC content has resulted in larger amount of unmelted TiC particles that are uniformly distributed in the alloy matrix to contribute towards marginal improvement in hardness, strength and wear resistance. However, the ductility was adversely affected.

Wang *et al.* (2007) used Ti64 wires and TiC powder to fabricate Ti64/TiC composites. In this study, the TiC content was varied from 8 to 74 vol%. While the mechanical characterization results showed better yield and ultimate strengths for 8 vol% TiC addition, but the ductility was adversely affected. The wear resistance of TMCs improved till 15 vol% TiC addition.

Gu *et al.* (2011) investigated the properties of Ti/TiC composites processed using selective laser melting of ball-milled Ti-15 wt%TiC composite mixture. In this study, the energy density input was found to significantly affect the microstructural evolution and the mechanical properties of developed composites. While the maximum energy density ($\sim 350 \text{ J/mm}^3$) produced a finer microstructure with uniformly distributed TiC particles, coarser dendrites and reinforcement agglomerates were reported for lower energy density levels. Similarly, better mechanical properties were achieved for energy densities more than 120 J/mm^3 . However, the mechanical properties were found to deteriorate when the energy density was significantly higher than 350 J/mm^3 .

The authors also investigated the influence of TiC content on the properties of Ti/TiC composites (Gu *et al.*, 2012). It was found that the increasing TiC content has a negative impact on the densification behavior as the melting and consolidation of the Ti-matrix along with TiC reinforcement becomes increasingly difficult. While the composite containing less than 15 wt% TiC showed better reinforcement distribution within the fine lamellar structured matrix, clustering was reported beyond 17.5 wt%TiC addition. Similarly, Kun *et al.* (2017) also reported the enhanced tensile strength of Ti/TiC nanocomposites due to the formation and uniform dispersion of nanoscale SiC during the SLM process.

Titanium boride reinforced Ti-MMCs were produced through the LENS processing of the elemental mixture containing Ti and B particles (Banerjee *et al.*, 2005). Microstructural characterization of the deposited composites showed fine microstructure with uniformly distributed TiB particles due to faster cooling rates in as-deposited state, whereas the microstructure was coarsened post heat treatment. Hu and Cong, (2018); Hu and Ning (2018) developed LENS deposited Ti/TiB composites from a blend of ball-milled Ti64 alloy and elemental boron. In this case too, a very fine distribution of needle shaped TiB precipitates with a clean interface and strong mechanical/chemical bonding with α/β Ti-matrix was reported which resulted in improved mechanical properties and wear resistance. In another study (Samuel *et al.*, 2008; Nag *et al.*, 2009), the same research group reported the LENS

processing and properties of TiB reinforced Ti-Nb-Zr-Ta composites prepared from the blend of elemental Ti, Nb, Zr, and Ta powder with TiB₂ particles. Here, the TiB precipitates exhibited two different morphologies, submicron sized (coarser) hexagonal shape and nanosized (finer) needle shape. A better wear resistance was also reported for the TiB/Ti-Nb-Zr-Ta composite.

Hu and Cong, (2018); Hu and Ning (2018) also investigated the effects of laser power on the microstructural features of TiB/Ti composites prepared from an elemental blend of 98.4 wt%Ti and 1.6 wt% B powder via the LENS technique. While the laser power of 175 W produced the discontinuous network of fine TiB precipitates, a fully continuous network of very fine TiB particles was seen in the composites produced using 200 W laser power.

Attar *et al.* (2014a) used a powder mixture of α -Ti and TiB₂ to produce Ti based MMCs via selective laser melting method. In this study, the chemical reaction between Ti and TiB₂ results in the in-situ formation of needle shaped TiB particles in the Ti-matrix as shown below.

While the microstructural characterization results reported the distribution of much smaller sized TiB precipitates in the SLM processed composite when compared to its cast counterpart, the hardness and compressive properties were found to be similar (Attar *et al.*, 2014).

In a similar study (Attar *et al.*, 2015a), the same research group also investigated the influence of composite powder processing. The composites were from sets of powder: one milled for 2 h duration and the other milled for 4 h. While the use of 2 h milled powder produced more uniform powder deposition due to better sphericity of powders and associated flowability, the composites prepared from 4 h milled powder exhibited higher porosity levels. Also, the compressive properties were superior in case of the

Table 2 Tensile properties of AlSi10Mg MMCs reported by (Aversa *et al.*)

Composition	Porosity	Young's modulus (GPa)	Yield strength (MPa)	Ultimate strength (MPa)	Ductility (%)
AlSi10Mg	0.4	72.3 $\pm$ 2.6	255 $\pm$ 1	383 $\pm$ 2	6.7 $\pm$ 0.2
AlSi10Mg + 1 wt% nano-TiB ₂	0.8	74.6 $\pm$ 0.8	161 $\pm$ 2	289 $\pm$ 2	8.5 $\pm$ 0.6
AlSi10Mg + 10 wt% micro-TiB ₂	2.0	83.6 $\pm$ 1.5	188 $\pm$ 5	318 $\pm$ 10	8.5 $\pm$ 1.8
AlSi10Mg + 0.5 wt% nano-MgAl ₂ O ₄	0.7	73.1 $\pm$ 1.7	198 $\pm$ 1	327 $\pm$ 2	8.3 $\pm$ 0.8

Note: Aversa, A., *et al.*, 2017. Microstructural and mechanical characterization of aluminum matrix composites produced by laser powder bed fusion. *Advanced Engineering Materials* 19. Available at: <https://doi.org/10.1002/adem.201700180>.

composite made using 2 h milled powder. The results of nano-indentation also showed better nanohardness and elastic modulus (Attar *et al.*, 2017).

In a similar study, (Kang *et al.*, 2016) used pure Ti and CrB₂ powder in the SLM process to fabricate Ti composites with in-situ TiB particles exhibiting better microhardness and wear resistance.

Recently, Chen *et al.* (2017) evaluated the wet corrosion properties of TiB/Ti composites using electrochemical measurements in Hank's solution at body temperature. The results showed a broader passive region and a better corrosion resistance due to the presence of TiB, and unmelted TiB₂ particles which acted as micro cathodes forming multiple galvanic couple with α -Ti matrix serving as anode.

In a latest study, (Xia *et al.*, 2017) SLM processed a ball-milled composite mixture of (TiC + B₄C). Here, the reaction between Ti and B₄C particles resulted in the in-situ formation of whisker and granular like TiB and TiC precipitates, which were evenly distributed in the α -Ti matrix to impart hardness and strength. Also, the increasing energy density in this case contributed towards larger TiB and TiC phases.

Table 3 Mechanical properties of LENS processed TiC reinforced Ti composites

Material	Hardness (HV)	Yield strength (MPa)	Ultimate strength (MPa)	Elongation (%)
Pure Ti	260	520	585	19
Ti + 10 vol% TiC	301	520	575	2.5
Ti + 20 vol% TiC	336	515	590	1.5
Ti + 40 vol% TiC	503	–	–	–
Ti64	320–394	907	956	10.8
Ti + 8 vol% TiC	–	1041	1075	0.3

Using the LENS process, Balla et al. (2012) produced TiN reinforced Ti- composites with varying TiN amounts (5%–40%). The developed composites were investigated for their in-vitro wear resistance and biocompatibility. The results highlighted their suitability as potential wear resistant coatings for load bearing biomedical implants.

Recently, Das et al. (2012), (2014) fabricated (TiB + TiN) reinforced Ti-composite coatings using Ti64 matrix and varying amounts of BN powder via the LENS process. Here, the increase in BN content and the laser energy resulted in increasing amount of TiB and TiN precipitates for better hardness, Young's modulus and wear resistance compared to the Ti64 base alloy. Similarly, in a recent study Himanshu and coworkers (Sahasrabudhe et al., 2015, 2016) reported the in-situ formation of TiN and Ti₂N phases during the remelting of Ti substrate in nitrogen rich atmosphere to produce nitride rich composite coatings with better micro-hardness and wear resistance.

Additive Manufacturing of Nickel Based Metal Matrix Composites

Nickels based alloys are widely used in aerospace, power generation, marine and petrochemical industries. (Li et al., 2009; Liu et al., 2010) used the direct laser fabrication technique to produce pure Ni based composites containing upto 60 vol%. TiC wherein the increasing the amounts of TiC improved the hardness and wear resistance. Cooper et al. (2013) investigated the effects of ceramic reinforcements such as Al₂O₃, SiC, TiC on the properties of Inconel superalloy. The results showed mechanical properties betterment due to SiC and TiC reinforcements, although prominent cracking issues were seen in SiC reinforced composites. However, the addition of Al₂O₃ had no appreciable effects.

In a similar study, Hong et al. (2015a) studied the laser energy effects on the properties of ultrafine TiC particle reinforced IN625 composites. While the laser energy of 33 KJ/m lowered the densification behavior due to insufficient melting and residual porosities, the energy input above 100 KJ/m produced near dense composites with uniformly distributed ultrafine and smooth TiC reinforcements. Similarly, the mechanical property characterization results revealed enhanced strength and reduced wear rate due to significant grain refinement. However, the energy input of 160KJ/m caused coarsening of primary columnar dendrites due to excessive thermal energy input. Similar results were also reported by (Cao and Gu, 2015; Cao et al., 2017) in which the columnar dendrites were transformed into cellular structures by varying the ratio between temperature gradient and the solidification velocity. In a similar study, Zheng et al. (2010) reported the positive influence of Ni coating on the flowability of TiC particles leading to better interfacial integrity.

Table 5 Properties of AM processed Fe-MMCs

Materials	Microhardness	Wear rate (mm ³ /Nm)
Pure 316 L	220 HV _{0.1}	9.865×10^{-4}
316 L + 2.5TiB ₂ (mixed)	300 HV _{0.1}	–
316 L + 2.5TiB ₂ (ball milled)	300 HV _{0.1}	6.276×10^{-4}
316 L + 5vol%TiB ₂ (ball milled)	320 HV _{0.1}	4.489×10^{-4}
316 L + 10vol%TiB ₂ (ball milled)	600 HV _{0.1}	0.744×10^{-4}
316 L + 15TiB ₂ (mixed)	570 HV _{0.1}	0.0055×10^{-4}
316 L + 15vol%TiB ₂ (ball milled)	610 HV _{0.1}	0.0019×10^{-4}
316 L + 15vol%TiB ₂ (ball milled, HIP 1) ^a	310 HV _{0.1}	0.992×10^{-4}
316 L + 15vol%TiB ₂ (ball milled, HIP 2) ^b	420 HV _{0.1}	1.613×10^{-4}
316 L + 2.5 vol% micro-TiC (ball milled)	290 HV _{0.2}	9.696×10^{-4}
316 L + 2.5 vol% nano-TiC (ball milled)	290 HV _{0.2}	9.431×10^{-4}
316 L + 5 vol% micro-TiC (ball milled)	310 HV _{0.2}	8.573×10^{-4}
316 L + 5 vol% nano-TiC (ball milled)	310 HV _{0.2}	7.770×10^{-4}
316 L + 10 vol% micro-TiC (ball milled)	335 HV _{0.2}	7.338×10^{-4}
316 L + 10 vol% nano-TiC (ball milled)	365 HV _{0.2}	4.304×10^{-4}
316 L + 15 vol% micro-TiC (ball milled)	390 HV _{0.2}	3.555×10^{-4}
316 L + 15 vol% nano-TiC (ball milled)	405 HV _{0.2}	3.106×10^{-4}
H13	748 HV _{0.2}	22.6×10^{-6}
H13 + 15 vol% TiB ₂ (ball milled)	759 HV _{0.2}	1.268×10^{-6}
H13 + 15 vol% TiB ₂ (ball milled, after HIP 1) ^a	834 HV _{0.2}	1.96×10^{-6}

^aHIP 1: HIP at 1150°C, 207 MPa for 2 h, followed by rapid cooling to 200°C at 100°C/min.

^bHIP 2: HIP at 1150°C, 207 MPa for 2 h, followed by rapid cooling to 900°C at 50°C/min and held for 2 h, followed by rapid cooling to 200°C at 100°C/min.

Hong *et al.* (2015b) also reported an improvement in the high temperature oxidation resistance of TiC/IN625 composites due to the combined presence of TiO₂ and Cr₂O₃ phases while the oxidized surface of IN625 was composed of just Cr₂O₃ precipitates. However, the oxidation attack increased at service temperatures beyond 800°C due to unfavorable oxidation of Cr₂O₃ to CrO₃.

Functionally graded IN690 composites reinforced with TiC particles were prepared by laser deposition (Wilson and Shin, 2012). In this study, the increasing amounts of TiC particles upto 30 vol% refined the matrix microstructure without getting dissolved at high temperatures. Using the method of selective laser melting, BN particles reinforced IN718 composites were also fabricated by (Kim *et al.*, 2017) and the results showed improvement in mechanical properties and thermal resistance upon BN addition.

TiC particles reinforced IN718 composites were also fabricated and the effects of laser energy density on the densification, microstructure and mechanical properties were studied (Hong *et al.*, 2013; Gu *et al.*, 2014). While the use of 350 J/mm³ laser energy density produced a dense microstructure with large amounts of smooth TiC phases, the lower energy density of 280 J/mm³ caused significant porosity. On the other hand, an optimal energy level of energy density produced a coherent interfacial layer of (Ti,M)C phases of thickness 0.8–1.4 μm (Hong *et al.*, 2013). Shi *et al.* (2016) also confirmed these observations through simulations and experimental validations. Here, the variation in laser power significantly affected the microstructural evolution, the variation in scan speed showed negligible changes. While the combination of high laser power (150 W) and low scan speed (50 mm/s) produced a wide and shallow cross-sectioned melt pool, the combination of low laser power (75 W) and high scan speed (300 mm/s) was energy efficient in the z-direction. On the other hand, the combination of 150 W laser power and 100 mm/s scan speed produced sound metallurgical bonding between the tracks and layers.

In a similar study, Rong and Gu (2016) developed WC/Ni- composites with a graded interfacial layer structure of (W,M)C where M = Ni,Cr,Fe surrounded by a diffusion layer of (W,M)C where M = Ni,Cr,Fe,Nb at an optimal energy density of 242 J/m.

Additive Manufacturing of Ferrous Based Metal Matrix Composites

The feasibility of using AM techniques to fabricate TiC reinforced Fe- MMCs was first study by (Gård *et al.*, 2006). Significant thermal cracking was observed due to increasing thermal expansion coefficients upon TiC dissolution and subsequent FCC - BCC phase transformations. Although the lesser TiC content (30 wt%) produced crack free composites, porosity was significantly high.

Song *et al.* (2014) in a similar study employed the SLM method to fabricate SiC/Fe composite from the mixture containing micron sized Fe and SiC powders. However, the microstructural results showed the uniform distribution of nanosized SiC particles due to the dissolution and subsequent precipitation of SiC phases, along with needle shaped martensite and partial pearlite phases. The same authors also explored the influence of hybrid (micro + nano) SiC particle addition and reported significant improvement in mechanical properties compared to pure Fe processed using similar method (Song *et al.*, 2013).

In a similar study, (Wei *et al.*, 2015) SLM processed the nano-hydroxyapatite (HA) particles reinforced stainless steel composites with an aim of understanding the effects of reinforcement volume fraction and the laser process parameters. It was observed that the high n-HA content resulted in significant particle clustering and cracks at melt pool boundaries which were improved upon increasing the laser scan speed. The superior mechanical properties of n-HA/SS composites reported in this study thus highlights the application potential as biomedical scaffolds. (Hao *et al.*, 2009) also developed HA reinforced 316 L composites using SLM. Here, since the reinforcement addition affected the laser energy input and the densification of bulk composites, the laser scanning procedure was duplicated to avoid balling effects and to facilitate better interfacial bonding.

Recently, (Almangour *et al.*, 2016b,c) employed the SLM method to fabricate SS composites containing different amounts of TiB₂ particles and reported that the optimum TiB₂ content of 10 vol% produced a homogeneous distribution of nano-ring like TiB₂ structures along the grain boundaries. The authors also investigated the influence of powder preparation and found that the particle size got significantly reduced after 8 h of ball milling (Almangour *et al.*, 2017b). Also, the use of ball milled powder in the SLM process resulted in better mechanical properties and wear resistance when compared to the composites made with just-mixed powder. However, the HIP-post processing of bulk composites resulted in high temperature grain coarsening and associated strength loss. Similar observations were also reported by the same authors for the TiC particles reinforced 316 L SS composites made using the powders of different starting size (Almangour *et al.*, 2016a, 2017a).

In another study, the same authors investigated the properties of TiB₂/H13 steel nanocomposites where the powder raw materials were ball milled prior to ball-milling (Almangour *et al.*, 2017c). Here, the microstructure of as-built nanocomposite was composed of very fine equiaxed grains and homogeneously dispersed TiB₂ particles within the grains and along the grain boundaries. The mechanical properties results showed better strength and hardness compared to unreinforced H13 base alloy. A further enhancement in hardness was reported post HIP-treatment. Similar results were also reported for TiC/H13 nanocomposites. (Almangour *et al.*, 2016b,c).

Additive Manufacturing of Copper Based Metal Matrix Composites

Copper based MMCs find excessive applications in electronics and semiconductor packaging. This section reviews the attempts made so far on the additive manufacturing of copper-based metal matrix composites. Tungsten has been widely used as the reinforcement in Cu-MMCs. Gu and Shen (2008) used the DMLS technique to consolidate the mixture of W + Cu powders and reported that the increase in elemental Cu content up to 60% resulted in a better densification due to increased liquid content. However, a further increase affected the melt pool stability to cause significant balling.

In a similar study, Gu and co-workers (Gu and Shen (2006), (2007), 2009a; Gu *et al.* (2008) processed the WC-Co/Cu composites using the laser sintering technique to understand the effects of laser energy input in terms of laser power, scan speed, layer thickness and hatch spacing. While the combination of laser power more than 400 W and scan speed greater than 0.06 m/s resulted in balling, a better densification was achieved for energy densities 0.16 and 0.23 KJ/mm³. Similarly, the reinforcement distribution was found uniform only when a minimum scan speed of 0.4 m/s and a maximum layer thickness of 0.3 mm were used for laser power less than 700 W (Gu *et al.*, 2008).

The same authors also investigated the effect of reinforcement (WC-Co particles) content and reported that the addition of 30 wt% reinforcement resulted in superior hardness of bulk composites due to improved reinforcement distribution and interfacial integrity (Gu and Shen, 2007). On the other hand, while the lower amounts of 20 wt% reinforcement caused severe balling due to melt-pool superheating, significant particle cluster due to poor melting and associated higher matrix' viscosity was recorded for higher amounts of 40 wt% reinforcement. The microstructural results also report two distinct reinforcement morphology: (1) partially dissolved – smooth and (2) completely dissolved – refine structures (Gu and Shen, 2007; Gu *et al.*, 2008).

Gu and Shen (2009b) also reported that the addition of 5 wt% RE-Si-Fe resulted in a better densification and the uniform distribution of WC reinforcement particles in WC-Co/Cu composites to contribute towards mechanical properties improvement. In a similarly study (Gu *et al.*, 2007), the same authors investigated the effects of 1 wt% La₂O₃ addition and reported an improvement in the relative density of bulk composites by 11.5% alongside microstructural refinement due to better distribution of the reinforcement phases. The same was attributed to the reduction in the melt pool surface tension and increased particle stimulated nucleation and further resistance to grain growth.

Lu *et al.* (2000) processed the elemental mixtures of Cu-Ti-C and Cu-Ni-Ti-C in a CO₂ laser assisted AM process to produce respective MMCs. While the in-situ formation of TiC phases was common for both the cases, a refined microstructure with better surface characteristics was reported for the Cu-Ni-T-C composites. In a similar study, Bhat *et al.* (2011) fabricated CNT reinforced Cu-10Sn alloy using a high energy laser where the addition of CNTs improved the mechanical and thermal properties. However, significant damage to CNT were also reported in this study.

Summary and Recommendations

In this article, the research progress on the additive manufacturing of metal matrix composites is summarized. The review of available literature suggests that only a selected few reinforcements such as SiC, TiC, TiB, TiB₂, BN, Al₂O₃ and to some extent in-situ developed compounds have been used repeatedly in most of the metal alloy matrices, although there are several hard and strong ceramic/metallic reinforcements found to be suitable. Recently, there were also few attempts made to fabricate CNT reinforced Al and Ti matrix composites. However, the CNTs were damaged upon interaction with the high energy laser source.

It was also found that the end properties of additively manufactured MMCs such as hardness, strength and wear resistance are generally superior than that of the unreinforced matrix alloy and in most cases, the processing condition along with the type and volume fraction of reinforcement played a significant role in the densification, microstructure and mechanical properties of additively manufactured MMCs. However, other properties such as high temperature mechanical properties, fatigue and creep require extensive attention. Currently, there are two simultaneous research approaches practiced in metal additive manufacturing: (1) on the pre-/ post-processing front and the other (2) on the actual AM processing methods.

While there has been a significant progress on the heat treatment of metallic alloys and metal matrix composite materials in general, literatures specifically applied to additively manufactured composites are meager and most of them are residual stress relaxation and age hardening related. Similarly, there has been some interest in the development of new materials that can be processed in commercial AM machines. On the other hand, the production of defect free powders and the development of stringent qualification norms are emerging. However, the AM methods are so far successful in producing dense parts through the optimization of process parameter window although the raw material powders do not fully comply with the process requirements. Similarly, the pre-processing of powder precursors through ball milling or mechanical alloying also receive extensive attention with regards to AM of MMCs.

With respect to processing, the feasibility and efficiency of specific AM processes receive great research interest. Although multiple studies have focused on the influence of print process parameters, extensive research efforts are required to deduce a deeper knowledge on microstructural evolution and the structure-property relationships. Especially, the size effects relating the test coupon properties with that of the actual parts and intricate features such as lattice structures need further research attention. In addition, advanced materials design and analysis tools are also needed to completely exploit the potential of AM process for greater industrial adoption.

Some of the critical challenges faced can be summarized as follows: (1) pre-processing of composite powder mixture: It is essential to prepare the composite powder mixture with required particle size and shape distribution as they cannot be readily obtained from the market, (2) unstable melt pool due to larger difference between the melting points of matrix and reinforcement material, (3) processing defects such as cracks and residual porosity due to poor densification and solidification conditions, and (4) need for post processing heat treatment due to faster cooling rates and the Young's moduli difference resulting in larger thermal residual stresses.

Despite these limitations, additive manufacturing of MMCs provide multiple benefits in terms of design flexibility and materials processing. Hence the development of AM composite technologies requires adequate attention to ensure process reliability and applicability.

Introduction

Grain size is a key microstructural factor that determines the mechanical properties of metallic materials. Among different metal working processes, methods involving grain refinement are promising for improved strength and fracture toughness. While grain refinement in conventional thermo-mechanical processes often leads to an average grain size in the order of few microns, severe plastic deformation (SPD) methods are capable of producing ultrafine or nanocrystalline microstructure (see Fig. 1) that offers multi-fold increase in strength properties.

SPD describes a group of metal-working processes that involve very large strains (von Mises strain in excess of 2) and complex stress states that result in large volumes of defect densities to generate nano-crystalline or ultrafine microstructure and the key feature is that the external dimensions of the workpiece do not change significantly. Unlike conventional metal working processes that follow a continuous strain path to result in a fibrous or cellular sub-grain structure with a large volume of low angle grain boundaries, SPD techniques offer possibility to change the strain path that promotes high angle boundaries and granular (sub) structures during deformation.

Presently, there are various SPD techniques applicable for bulk batch and continuous billets; for rods, plates, tubes, and sheet materials; for one-step and multi-step processing; and for SPD of surfaces and thin cross-sections. However, they are being carried out on a laboratory scale using small samples, simple tools, and labor-intensive procedures that do not meet industrial requirements. Therefore, their applicability to products, especially those with a complex shape and large size are limited.

Types of Severe Plastic Deformation Methods

Some of the examples of severe plastic deformation methods include: (1) equal channel angular processing or extrusion (ECAP), (2) high pressure torsion (HPT), (3) multi-axial forging (MAF), (4) accumulative roll bonding (ARB), and (5) repetitive corrugation and straightening (RCS). While ECAP, HPT, and MAF methods are applicable for bulk materials, ARB, and RCS are used for sheet metal processing.

Equal Channel Angular Pressing (ECAP)

ECAP is one of the most common SPD methods. It was originally invented by Segal in 1972 (Segal, 1999, 1974). This method is widely explored for manufacturing ultra-fine grained products including fasteners like screws and screw rivets commonly used in the assembly of aluminum components for aircraft and other structures, elements for aircraft fuselages, sections of various size and shape and sheets for assemblies operating in corrosive environments and at cryogenic temperatures, and complex-shaped parts produced by superplastic forming. This method improves the strength and ductility of metal matrix composites by means of grain refinement and favorable crystallographic texture modification. Fig. 2 shows an example of microstructural changes in SiC particles reinforced AZ91 composites after 16 pass ECAP performed using a 90° rotary die.

As schematically shown in Fig. 3, ECAP processing involves pressing or extrusion of the material through a die with identical inlet and outlet cross sections, intersecting at an angle " ϕ " that varies between 60 and 135°. Since the total strain imposed during ECAP determines the grain refinement, the channel angle is considered critical and most experimental works report the use of channel angles between 90 and 120°. When the fillet radius is zero, the work piece undergoes simple shear. Some of the ECAP procedures also involve a rounded corner with angle ψ . The plastic strain accumulated during ECAP processing can be calculated using Eq. (1) (Iwahashi *et al.*, 1996; Valiev *et al.*, 2006). Therefore, for $\phi = 90^\circ$ and $\psi = 0^\circ$, the equivalent plastic strain is 1.155.

$$\text{Plastic strain accumulated during ECAP, } \bar{\epsilon} = \left[\frac{2 \cot\left(\frac{\phi}{2} + \frac{\psi}{2}\right) + \psi \operatorname{cosec}\left(\frac{\phi}{2} + \frac{\psi}{2}\right)}{\sqrt{3}} \right] \quad (1)$$

Other significant factors that affect the strain accumulation and grain refinement during ECAP processing include pressing temperature, pressing speeds, the number of passes and rotation strategy. Fig. 4 shows the effects of inter-pass rotation schemes (Route A (no rotation), Route B (90° back and forth rotation between passes), Route C (180° rotation between passes)) on the microstructure of ECAP processed Mg-4Al-1Ca alloy. In general, the ECAP process is repeated for multiple times and the work piece is often rotated between passes in order to cause shearing on different planes. While the material volume gets restored to its initial shape after a specific number of passes (after every 2nd pass in route C and after 4th pass in Bc route), the strain path varies between ECAP passes and the changes depends on the die angle ϕ and the rotation angle φ . Here, the equivalent strain in

Fig. 1 Microstructure of high purity aluminum (a) before and (b) after severe plastic deformation processing. Adapted from Kawasaki, M., Horita, Z., Langdon, T.G., 2009. Microstructural evolution in high purity aluminum processed by ECAP. *Mater. Sci. Eng. A* doi:10.1016/j.msea.2009.06.032. The color of grains corresponds to the orientations as presented in the unit triangle and the grain boundaries denoted by black and red lines correspond to low ($2-15^\circ$) and high-angle ($>15^\circ$) misorientations.

Fig. 2 IPF (a, c) and grain size (b, d) of ECAP processed $\text{SiC}_p/\text{AZ91}$. (a, b) 4P; (c, d) 16P. Adapted from Xu, Q., Ma, A., Saleh, B., *et al.*, 2020. Enhancement of strength and ductility of $\text{SiC}_p/\text{AZ91}$ composites by RD-ECAP processing. *Mater. Sci. Eng. A* 771, 138579. doi:10.1016/j.msea.2019.138579.

multiple pass processing can be calculated by multiplying the Eq. (1) by the number of passes. For example, while single pass with $\Phi = 90^\circ$ results in an equivalent strain of 1.155, four passes using Route Bc produce an overall strain ~ 4 to develop a fairly uniform grain structure over a range of alloys. Thus, it can be understood that the individual strain path plays an important role in controlling the strain accumulation, microstructural evolution and the end mechanical properties (Minárik *et al.*, 2017). In this regard, some of the recent literatures also highlight the requirement of strains greater than 6 to eliminate low angle grain boundaries and result in a finer grain size in the order of few to few hundred nanometers (Valiev *et al.*, 2000).

Fig. 3 (a) Schematic representation of ECAP process and (b) an ECAP die used to process copper alloy. Adapted from Ref. Sanusi, K.O., Makinde, O.D., Oliver, G.J., 2012. Equal channel angular pressing technique for the formation of ultra-fine grained structures. *S. Afr. J. Sci* 108, Article 212. doi:10.4102/sajs.v108i9/10.212.

Langdon *et al.* (2000) and Furukawa *et al.* (2000) showed that the level of grain refinement achieved by shear through 90° dies is significantly high when compared to die angles greater than 90°.

Despite the advantages as mentioned above, ECAP processing is mostly limited to laboratory scale as a substantial volume of material at the leading and trailing edge does not undergo large deformation. Similarly, the larger frictional stresses at the entrance of the die limits the work piece length. To reduce stress concentration, Segal *et al.* (1995) and Semiatin and DeLo (1999) modified the die design by moving the floor of the exit channel along with the work piece. Alternatively, Chakkingal *et al.* (1998) proposed pulling the work piece through a die as shown in Fig. 5. While the drawing operation eliminates the frictional force at the entrance of the die and reduced the overall metal forming force, one of the serious limitations is that the stress required to draw the material should not exceed the tensile strength.

High Pressure Torsion (HPT)

In high-pressure torsion (HPT), the material is subjected to severe plastic deformation by a simultaneous action of high pressure and torsional strain. A vertical pressure of around 5 GPa is applied to press down a small disk of the material (usually about 20 mm in diameter and about 0.2–0.5 mm in thickness) on the support and the plunger is then rotated to apply a torsional strain as shown in Fig. 6. Hence, the frictional force between the plunger and the sample, and the sample and the anvil, help to shear the material (Iwahashi *et al.*, 1996).

Here, the effective strain is given by:

$$\varepsilon_{\text{eff}} = \gamma / \sqrt{3} \quad (2)$$

where γ is the shear strain achieved for “N” number of turns which can be calculated as follows:

$$\gamma = \frac{2rN\pi}{l} \quad (3)$$

r and l are the radius and thickness of the disk, respectively.

From Eqs. (2) and (3), the shear strain increases with increasing radius, thus making the deformation inhomogeneous. However, existing literature highlights the fact that the microstructure tends to homogenize with increasing number of rotations as inferred from microhardness and grain size measurements (Valiev *et al.*, 2006). Therefore, the actual deformation in HPT is complex compared to classical torsion (see Fig. 7).

Multiaxial Forging (MAF)

Multiaxial forging (MAF) or compression (MAC) involves repeated uniaxial compression of materials, sequentially along the three orthogonal axes i.e., the loading direction is changed through 90° between successive compressions as shown in Fig. 8. Although this method can produce fine microstructures, it requires surface preparation unless a confined channel die that offers plane strain compression is used to produce a higher effective strain (for the same reduction in height) compared to uniaxial compression. While the open channel die has the limitation of non-uniform deformation due to bulging of free surfaces and early cracking, the confined channel die ensures no bulging and the sample conforms to the shape of the die after each pass resulting in more uniform deformation (Sanusi *et al.*, 2012).

Accumulated Roll Bonding (ARB)

It is a solid-state process originally invented by Tsuji *et al.* (1999) in 1999 to fabricate multi-layered composite structures. In this process, a stack of two sheets with equal thickness is subjected to plane strain rolling which binds them together and reduce the

Fig. 4 (a) Schematic of ECAP routes. (b–c) Initial microstructure (IPF maps obtained on the (b) cross-section and (c) longitudinal section) of extruded Mg-4Al-1Ca alloy. Microstructure after 8 passes ECAP via (d) route A, (e) route B_C and (f) route C. Adapted from Refs. Sanusi, K.O., Makinde, O.D., Oliver, G.J., 2012. Equal channel angular pressing technique for the formation of ultra-fine grained structures. *S. Afr. J. Sci* 108, Article 212. doi:10.4102/sajs.v108i9/10.212. Minárik, P., Krajčák, T., Srba, O., *et al.*, 2017. Chapter 2 – Mechanical properties and microstructure development in ultrafine-grained materials processed by equal-channel angular pressing. In: Cabibbo, M. (Ed.), *Severe Plastic Deformation Techniques*. IntechOpen. doi:10.5772/intechopen.68965.

thickness by 50%. The rolling process is repeated for multiple times by cutting the rolled sheet in half and stacking up to initial thickness to accumulate the large plastic strains and the alignment of sheets can be changed between each cycle (see Fig. 9(a)). There are a number of parameters starting from material type (similar or dissimilar sheet metals and the reinforcement), surface properties (surface roughness, presence of moisture, contaminants, oxides, lubricants, etc.) and rolling conditions (percentage reduction, rolling speed, rolling temperature, number of layers, etc.) that affect the plastic deformation in ARB process (Tsuiji *et al.*, 2003; Ghalehbandi *et al.*, 2019). While available literature reports significant grain refinement to less than few microns in materials such as steel, aluminum alloys, copper, and nickel, edge cracks and inhomogeneous plastic deformation are also widely reported. The shear component is further enhanced by employing rolls of different diameter and rolling speed as in the case of asymmetric

rolling as shown in Fig. 9(b) which involves the simultaneous action of compression and shear. Fig. 10 illustrates the microstructure of ARB processed Al matrix composites reinforced with graphene oxide.

Repetitive Corrugated Straightening

Repetitive corrugated straightening (RCS) or constrained groove pressing (CGS) method imparts a large amount of plastic strain by repeated bending and straightening of the workpiece. While the bending step involved pressing of the sheet material using V-shaped dies as shown in Fig. 11, straightening involved pressing the corrugated sheet using flat dies. Therefore, the RCS method does not affect the overall dimension of the work piece and one of the major advantages of RCS method is that it can be easily adapted to the current industrial rolling facilities by incorporating corrugated teeth to the rollers.

Fig. 12 shows the microstructure of fine-grained Cu processed by RCS method. It highlights the high dislocations density in the Cu grains of size less than few hundred nanometers when compared to as-annealed condition (prior to RCS processing) with an average grain size of 765 μm (Huang *et al.*, 2001).

Continuous SPD Techniques

Unlike the SPD processes as discussed earlier where specific short-dimension specimens are used, latest developments focus on continuous techniques such as con-shearing, continuous severe plastic deformation, continuous repetitive corrugation and straightening etc. These continuous processes often combine the benefits of SPD and rolling methods as illustrated in Fig. 13 and are mostly applicable for sheet metal composites.

Adapted from Sabbaghianrad, S., Langdon, T.G., 2016. Developing superplasticity in an aluminum matrix composite processed by high-pressure torsion. *Mater. Sci. Eng. A* 655, 36–43. doi:10.1016/j.msea.2015.12.078.

Microstructural Evolution During Severe Plastic Deformation

Severe plastic deformation-induced grain refinement has been extensively studied for fabricating ultra-fine-grained (UFG) metals. In general, the grain refinement during SPD processing depends on several factors such as process parameters including plastic strain, strain rate, strain path, temperature, and materials properties including the crystalline structure, stacking fault energy (SFE) and initial grain size (Bagherpour *et al.*, 2019). According to Tao and Lu (2009), significant grain refinement can be achieved by increasing the strain rate and reducing the temperature. They also related the strain rate ($\dot{\epsilon}$) and temperature (T) using Zener Hollomon parameter ($Z = \dot{\epsilon} \exp(-Q/RT)$, where Q is the activation energy and R is the gas constant) and showed that the critical value of Z depends on the stacking fault energy (SFE) which determines the extent of deformation by dislocation slip or twinning. While the dislocation slip is dominant in high SFE materials, twinning governs the deformation in low to medium SFE (Kawasaki and Langdon, 2015a).

Fig. 8 Microstructural evolution during the multi-axial forging of WE43 magnesium alloy. Reproduced from Salandari-Rabori, A., Zarei-Hanzaki, A., Abedi, H.R., Lecomte, J.S., Khatami-Hamedani, H., 2018. Micro and macro texture evolution during multi-axial forging of a WE43 magnesium alloy. *J. Alloy. Compd* 739, 249–259. doi:10.1016/j.jallcom.2017.12.181.

Published literatures highlight the mechanism of dislocation dependent grain refinement mechanism in FCC structured Ni and Al with high stacking fault energy (SFE) values (in the range ~ 130 – 280 mJ/m^2) (Verlinden, 2004; Kawasaki and Langdon, 2015a; Cao *et al.*, 2018; Wang *et al.*, 2008). It consists of five stages as shown in Fig. 14. In the first stage, the dislocation cells and cell structures group together and form dislocation cell blocks which reduce in size at stage 2 due to the formation of microbands and the reorientation of early formed dislocation cells. At stage 3, the dense microbands along with the increase in misorientation angles and the continuous reduction of cell block sizes result in the formation of a large amount of lamellar sub-grains enclosed by lamellar boundaries which tend to align parallel to the shear strain direction. The increasing strain then sharpens the inter-connecting boundaries to result in a finer lamellar structure in Stage 4 and the grain refinement reaches a steady state with mostly equiaxed grains at Stage 5.

In case of low SFE materials like Cu–30 wt% Zn alloy (with a very low SFE of ~ 7 mJ/m^2), the deformation process is primarily governed by the formation of nano-twins (Cao *et al.*, 2018; Zaynullina *et al.*, 2019; Zhang *et al.*, 2011). The mechanism is schematically illustrated in Fig. 15. Here, the coherent twin boundaries that are effective in restricting the dislocation slips are transformed into grain boundaries. Therefore, the steady state grain size of SPD processed low SFE materials are comparable to that the twin boundary spacing. However, in some cases, as very thin nano-twins are formed at the early stage of deformation which upon interaction with the primary coherent twin boundaries result in de-twinning which then leads to a slightly larger grain size (Fig. 16). Since, the mode and extent of deformation are also affected by the initial grain size, the grain refinement and grain growth mechanisms require a dynamic balance in SPD processing to achieve preferred grain size and grain orientation.

Fig. 9 Schematic of (i) accumulated roll bonding processes and (ii) asymmetric rolling setup. Adapted from Ref. Verlinden, B., 2004. Severe plastic deformation of metals. *Metal. -J. Metall* 11 (3), 165–182.

Mechanical Properties of SPD Processed Metal Matrix Composites

Mechanical property enhancement has been the primary driving force behind the development of advanced materials processing methods. Since SPD methods impose a large strain when compared to the conventional materials processing and shaping methods, they can produce bulk nanostructured materials that offer a better combination of mechanical properties including strength and ductility as shown in [Table 1](#).

In general, the mechanical properties of SPD processed materials are primarily affected by the microstructural characteristics (grain size, precipitates, phase transformation, crystal structure, etc.) that are affected by the intrinsic properties of the material and the processing/deformation conditions ([Dieter and Bacon, 1988](#); [Wagner et al., 2017](#)). During SPD processing, the high strain imposed on the material leads to high dislocation density and grain refinement ([Dieter and Bacon, 1988](#); [Callister and Rethwisch, 2007](#)). Therefore, strain hardening and grain boundary strengthening are the two major strengthening mechanisms operative in SPD processed materials. While the strengthening contribution ($\Delta\sigma_d$) resulting from dislocation accumulation or strain hardening is given by the Bailey–Hirsch relationship, Hall-Petch equation describes the strength increase due to strengthening by grain/twin boundaries ($\Delta\sigma_{HP}$) ([Cao et al., 2018](#); [Balogh et al., 2010](#)).

$$\Delta\sigma_d = M\alpha_T bG\sqrt{\rho_t} \quad (4)$$

$$\Delta\sigma_{HP} = k_{GB}D_B^{-1/2} + k_{TB}\lambda_{TB}^{-1/2} \quad (5)$$

where M – Mean orientation factor (dimensionless)

α_T – dimensionless constant between 0.3 and 0.5 depending on temperature.

b – Burgers vector in nm.

G – shear modulus in GPa.

ρ_t – Total dislocation density in m^{-2} .

k_{GB} – Hall Petch coefficient for GB strengthening in MPa/m.

D_B – Average grain size in nm.

k_{TB} – Hall Petch coefficient for twin boundary strengthening in MPa/m.

λ_{TB} – Average twin boundary spacing in nm.

In this regard, the factors including SFE and crystal structure of the materials play an important role ([An et al., 2009](#); [Qu et al., 2009](#)). For example, twin boundary (TB) strengthening is dominant in low SFE materials as the deformation is mostly twinning controlled and the TB spacing is significantly small compared to the GB spacing. Further, it is also widely reported that the change in dominant deformation mechanism from dislocation slip to twinning with decreasing SFE improves the strength properties.

With respect to crystal structure, because of the larger critical resolved shear stress value, BCC metals tend to have larger Hall Petch coefficients and their GBs are relatively more effective in controlling the dislocation slips than the HCP and FCC metals.

Similarly, the interplay between dislocations and precipitates also offer strengthening effects. While the incoherent precipitates improve the strength by Orowan bypassing mechanism, the coherent and semi-coherent precipitates offer (1) coherency strengthening ($\Delta\sigma_{cs}$), (2) modulus mismatch strengthening ($\Delta\sigma_{ms}$) and (3) order strengthening ($\Delta\sigma_{os}$) (Ma *et al.*, 2014; Fribourg *et al.*, 2011). Therefore, for precipitation strengthening based on the dislocation shearing mechanism, the sum of ($\Delta\sigma_{cs} + \Delta\sigma_{ms}$ or $\Delta\sigma_{os}$) will be significant.

$$\Delta\sigma_{orowan} = M \frac{0.4 G b \ln\left(\frac{2\bar{r}}{b}\right)}{\pi\sqrt{1-v} \lambda_p} \quad (6)$$

$$\Delta\sigma_{cs} = M \alpha_e (G \epsilon_c)^{\frac{1}{2}} \left(\frac{r f}{0.5 G b} \right)^{\frac{1}{2}} \quad (7)$$

$$\Delta\sigma_{ms} = M 0.0055 (\Delta G)^{\frac{1}{2}} \left(\frac{2f}{G} \right)^{\frac{1}{2}} \left(\frac{r}{b} \right)^{\frac{3m}{2}-1} \quad (8)$$

$$\Delta\sigma_{os} = M 0.81 \frac{\gamma_{apb}}{2b} \left(\frac{3\pi f}{8} \right)^{1/2} \quad (9)$$

where $\bar{r}$ – Mean cross section radius of a precipitate in a random plane in nm

In addition, the lattice friction together with the local strain field generated due to the difference in atomic radii of alloying elements also obstruct the dislocation slip, thereby leading to solid solution strengthening ($\Delta\sigma_{ss}$) (Fleischer, 1962).

$$\Delta\sigma_{ss} = M G b \varepsilon_{ss}^{3/2} \sqrt{C} \quad (10)$$

where ε_{ss} – dimensionless parameter that accounts for the local resistance to dislocation propagation, C – concentration of solute atoms in wt%.

Therefore, the overall yield strength can be determined by the sum of strengthening contributions from various mechanisms as shown below (Ma *et al.*, 2014):

$$\sigma_y = \sigma_o + \Delta\sigma_d + \Delta\sigma_{HP} + \Delta\sigma_{ss} + \Delta\sigma_p \quad (11)$$

where σ_o refers to the lattice friction stress

While most SPD processed materials possess very high strength, only a few with a high density of intragranular solute clusters and/or nano-sized second-phase particles, or a large number of coherent TBs that are effective in blocking the dislocations exhibit outstanding combination of strength and ductility (Table 1). Here the unique micro/nanostructure offers additional strain hardening capability to delay the localized plastic strain instability. Similar ductility improvements are also reported for gradient nanostructure (nanostructured surface layers and coarse-grained core) and hetero-structured (agglomerated coarse grains embedded within nanostructured matrix) materials (Wu and Zhu, 2017; Ma and Zhu, 2017; Fang *et al.*, 2011, 2014). The ductility of SPD processed materials is also improved by increasing the strain rate sensitivity. However, this approach is less effective as the strain rate sensitivity of most materials is relatively small at room temperature (Ovid'ko *et al.*, 2018).

In some cases, severe plastic deformation leads to super plasticity which refers to the capability of a material to undergo very large plastic deformation (Langdon, 1982). While the fundamental requirement for super plasticity in conventional polycrystalline materials involves grain boundary sliding that requires a fine grain size less than 10 μm and a homologous temperature above 0.5 T_m at strain rates between 10⁻³/s to 10⁻⁴/s, a classical dislocation glide mechanism will be active in metal matrix composites

Fig. 17 Elongation to failure plotted against strain rate for the MMC in the as-received condition and after processing by HPT through 10 and 20 turns. Adapted from Sabbaghianrad, S., Langdon, T.G., 2016. Developing superplasticity in an aluminum matrix composite processed by high-pressure torsion. *Mater. Sci. Eng. A* 655, 36–43. doi:10.1016/j.msea.2015.12.078.

and powder metallurgy processed materials at low temperatures ($<0.5T_m$) and high strain rates ($>10^{-2}/s$) (Kawasaki and Langdon, 2015a,b). An example of strain induced super plasticity in metal matrix composites is illustrated in Fig. 17.

Concluding Remarks and Recommendations

Published studies demonstrate the feasibility of lab scale SPD methods such as ECAP, HPT, MAF etc. to produce ultrafine grained materials. While the downscaling of SPD processes provides an opportunity to produce UFG wires and fibers, the upscaling is not evident although interesting adaptations such as asymmetric rolling, corrugation and straightening, con-shearing, continuous confined strip shearing, ECAP-conform etc. are being developed for the continuous production of fine grained materials. Therefore, it is now reasonable to anticipate the extensive application of UFG metal matrix composites. UFG materials find significant potential for applications under extreme conditions in aircraft systems, oil and gas industry, energy, high-performance sports, bio-medical, etc. One of the established examples include ECAP processing of Al and Cu sputtering targets in the fabrication of memory components for micro electro-mechanical systems (MEMS).

SPD processing leads to a significant increase in dislocation density which results in a unique micro/nanostructured architecture. In this regard, stacking fault energy plays a critical role. While the grain refinement in high SFE materials occurs by dislocation activities, the complex interplay between the dislocation slips and the deformation twinning or twin boundaries is responsible for the grain refinement in low SFE materials. Although the grain refinement resulting from SPD processing is often stable, grain coarsening in some cases results in bimodal grain size distribution. With respect to mechanical properties, mechanisms such as dislocation strengthening, grain boundary strengthening, precipitate and solid solution strengthening improve the strengths of SPD processed materials. Similarly, the unique microstructure resulting from SPD processing offers additional strain hardening capability and delays the localized plastic strain instability for moderate improvements in ductility. With adequate thermal stability, SPD processing also opens up the possibility for high strain rate and/or low temperature super plasticity.

While the improvement in strength properties of SPD processed materials have been investigated extensively, recent studies focus on the modification of SFE and the development of gradient nanostructure (nanostructured surface layers and coarse-grained core) and hetero-structure (agglomerated coarse grains embedded within nanostructured matrix) for improved ductility.

Introduction to Friction Stir Processing (FSP)

Friction stir processing (FSP) is a variant of the friction stir welding (FSW) process wherein a rotating non-consumable FSW tool is used to join the abutting metallic plates. The FSP is a solid-state material processing technique that is used to engineer the surface of the material using a rotating FSP tool. The FSP produces refined microstructure and thus enhances the mechanical properties, tribological properties, corrosion properties, fatigue resistance, etc., and eliminates defects without affecting the properties of the underlying bulk material. In FSP the non-consumable rotating tool having a profiled pin and a relatively large diameter shoulder is plunged into the surface of the work material and traversed across the surface of the material. Large surfaces are processed by rastering the transverse of the tool path. The material gets thermomechanically processed due to frictional heat between the FSP tool and surface of the material and flow of the plasticized material around the tool and consolidation by the ironing action of the shoulder of the tool. The schematic of the friction stir processing technique is shown in [Fig. 1](#). ([Sharma et al., 2015](#)).

Fabrication of Surface Composites (SCs) by FSP

The traditional techniques used for fabricating SCs involve molten metal (liquid phase) processing techniques like plasma spraying and laser melt treatment. These techniques are prone to deterioration of the properties of the composite caused by the reinforcement-matrix interfacial reaction. ([Pantelis et al., 1995](#); [Meng et al., 2013](#); [Sharma et al., 2015](#)).

In the initial stages of FSP, the SCs were fabricated by applying volatile slurry comprising of ceramic particles above the substrate over which the FSP tool plows through forming the SC. ([Mishra et al., 2003](#)). Currently, the practice is to fill the ceramic particles in a machined groove on the substrate. ([Arora et al., 2012](#)). To improve the homogeneity in the distribution of the reinforcing particles, the particles are filled in blind holes drilled on the substrate. ([Li et al., 2013](#)). To prevent the ejection of the reinforced particles from the holes a thin cover plate is used over the drilled substrate and subjected to FSP. ([Lim et al., 2009](#); [Avettand-Fènoël et al., 2014](#)). In some other approaches functionally graded SC was fabricated on AA6082-T6 using a consumable tool filled with reinforcement particles. ([Gandra et al., 2013, 2014](#); [Miranda et al., 2013](#)).

In another approach, a direct friction stir processing (DFSP) was applied on the AZ31 matrix. Here a hollow probe less tool filled with reinforcement particles was used to fabricate the SC. Here the particles flowed out of the hollow tool and get pressed into the substrate by the rotating transversing tool. ([Huang et al., 2014](#)).

Classification of Friction Stir Processed Surface Composites

The surface composites fabricated through friction stir processing are broadly classified into six types as given below: ([Sharma et al., 2015](#)).

- (1) Surface Nano-Composites.
- (2) Surface Micro-Composites.
- (3) Surface hybrid composites.
- (4) Surface-Powder metallurgy in-situ composites/Intermetallic Powder Composite.
- (5) Surface Metal Powder Composites/Surface Composites SCs.
- (6) Surface Bulk Composites.

Surface Nano-Composites

The addition of ZrO_2 of an average size of 40 nm to the surface of AZ31 alloy through FSP using an H13 hot work tool steel, pinless tool rotating at 1250 rpm and traversing at 20 mm/min and a tool tilt of 2.5 degrees was attempted. The exposure to more FSP passes resulted in the formation of ultra-fine grains which was attributed to the Zener-pinning effect. The ZrO_2 nanoparticles prevent the growth of the high-angle grains at high temperatures, by pinning the grain boundaries, thus increasing the hardness and tensile strength of the FSPed surface composite. Further, these fine grains offer resistance to the motion of dislocations and thus enhance the hardness and tensile strength of the surface composite ([Navazani and Dehghani, 2016](#)). This behavior conforms with the Hall-Petch type of equation. ([Chang et al., 2004](#)).

$$H_v = 40 + 72d^{-1/2} \quad (1)$$

Fig. 1 Schematic of friction stir processing technique. Reproduced from Sharma, V., Prakash, U., Kumar, B.V.M., 2015. Surface composites by friction stir processing: A review. *Journal of Materials Processing Technology* 224, 117–134. Available at: <https://doi.org/10.1016/j.jmatprotec.2015.04.019>.

Where H_v is the microhardness readings in the various zones of FSPed surface composite and d is the average grain size of the surface composite.

Sheets of aluminum-magnesium alloy AA5052 FSPed with TiO_2 nanoparticles of a mean diameter of around 20 nm using a H13 tool yielded good tensile strength and hardness. The high heat peaks in the advancing side due to severe plastic straining and deformation influenced the microstructure and mechanical properties of the surface nanocomposite. The higher ω/v ratio where ω is rotational speed and v is the traverse velocity; ensured uniform distribution of the nanoparticles in the AA5052 matrix ensuring the pinning of the grain boundaries and the associated formation of ultrafine grains and enhanced solid-state chemical reactions. Further, the grain size in the stir zone (SZ) was mainly influenced by the rotational speed, than the traverse velocity. (Khodabakhshi *et al.*, 2017).

The AZ61A billets incorporated with 5–10 vol% of SiO_2 nanoparticles of average diameter around 20 nm were processed through FSP using fixed pin FSP tool with a 2° tilt angle operating at a rotational speed of 800 rpm and advancing speed of 45 mm/min. With four passes it yielded a good distribution of the nano SiO_2 particles which react with the Mg in the matrix and forms Mg_2Si and MgO phase of 5–200 nm size. The nanocomposite exhibited a high strain rate superplasticity (HSR SP) of over 400% due to the uniform distribution of SiO_2 at elevated temperature occurring during the multiple passes of FSP (Lee *et al.*, 2006). The surface nanocomposite $\text{SiO}_2/\text{AZ31}$ produced through FSP exhibited grain refinement-associated formation of ultrafine grains and enhanced hardness. The nano SiO_2 particles of around 20 nm were FSPed at a rotating speed of 1200 rpm and a 50 mm/min travel speed. (Jiang *et al.*, 2013). The fine grain formation was attributed to the smaller particle interspacing (L). This is represented in Eq. 2. (Ardell, 1985).

$$L = d/2(2\prod/3V_f)^{1/2} \quad (2)$$

where

d is average particle diameter and V_f is particle volume fraction.

Hence according to Eq. 2, the ductility of the composite shall reduce as the V_f increases. Also, the L decreases with a reduction in d , and hence FSP improves the particle interspacing and breaking the reinforcement particles to a smaller size.

The underwater submerged FSP of AA5083/ Al_2O_3 surface composite produced a good reduction in grain size and enhanced mechanical properties. The Al_2O_3 nanoparticles of 80 nm and the shorter thermal cycle in the submerged FSP coupled with multiple FSP pass yielded enhanced properties. The enhanced mechanical properties were mainly attributed to the Hall-Petch effect than the Orowan mechanism. (Ashjari *et al.*, 2015).

In AZ31/ Al_2O_3 nano surface composite, the increase in frictional heat with the increase in rotational speed of the FSP tool caused the shattering of the nanoparticles and their uniform distribution, and the associated grain refinement with every pass of the multipass FSP cycle. Here dislocation pinning effect strengthened the composite. (Azizieh *et al.*, 2011). The presence of finely dispersed alumina (Al_2O_3) caused due to FSP limited the grain growth and resulted in ultrafine grain size as governed by Zener limiting grain size (d_z). (Martin *et al.*, 1997).

$$\text{Zener limiting grain size } d_z = 4r/3V_f \quad (3)$$

Where

r is the radius of the reinforcement particles and

V_f is the volume fraction of clustered reinforcement particles

The theoretical grain size of the surface composite layer is determined by the Zener-Holoman parameter.

The addition of Al_2O_3 particles to AZ91 alloy and fabrication of $\text{Al}_2\text{O}_3/\text{AZ91}$ nano surface composite using a square profiled FSP tool, rotating at 900 rpm speed and a traverse speed of 80 mm/min produced optimal results in a single FSP pass. It was observed that the grain size and the frictional temperature was reduced with a reduction in traverse speed. Also, higher traverse speed yielded a better distribution of the nano alumina particles and a decrease in grain size as per the Hall–Petch relationship. The evolved grain size could be related to Zener limiting grain size (d_z), which suggests that the dispersing of fine Al_2O_3 particles limits the grain growth, resulting in the formation of ultrafine grains in the nano surface composite. (Faraji *et al.*, 2011).

The incorporation of 40 nm size Al_2O_3 particles to the surface of AA7075 plates through FSP produced surface composite having enhanced hardness to the tune of double the original hardness after four FSP passes. (Refat *et al.*, 2016). Similarly while dispersing 50 nm-sized Al_2O_3 particles in 6082 aluminum alloy through FSP; the hardness increases 3 folds and a significant improvement in wear resistance was realized. This enhancement of hardness is attributed to strengthening mechanisms, viz. Orowan strengthening, grain and substructure strengthening, quench hardening caused by the dislocations generated to compensate the difference in thermal contraction between the matrix and the reinforcement particles, and work hardening effect caused by the mismatch in strain between the plastic matrix and the elastic reinforcement particles. The wear behavior of the matrix changed from abrasive to adhesive, whereas in the surface nanocomposite the wear is both adhesive and abrasive was attributed to the lowered coefficient of friction associated with reduced abrasive mode of wear (Shafiei-Zarghani *et al.*, 2009).

The multiple passes of FSP on nano sized Al_2O_3 of around 50 nm average particle size placed in shallow grooves resulted in finer grains in the Al matrix. The uniform dispersion of the nano Al_2O_3 particles yielded around three times increase in hardness. The Al/ Al_2O_3 nano surface layer (SCL) exhibits an abrasive mode of wear at loads of 20 and 40 N, whereas as the load increases to 60 N, the mode of wear is dominantly adhesive. (Shafiei-Zarghani *et al.*, 2011).

The coating of Al_2O_3 nanoparticles on Al2024 substrate through air plasma spraying and subjecting to FSP produces a surface nanocomposite having 600 μm penetration into the surface of the substrate. This surface nanocomposite exhibited enhanced bonding to substrate, hardness, and wear resistance. The wear mode involved delamination. (Zahmatkesh and Enayati, 2010).

The Cu/ SiC_p nanocomposite fabricated through the FSP route produced a 95% enhancement in the microhardness with the incorporation of 50 nm-sized SiC particles in the copper matrix. The frictional heat during FSP reached peak value with increased rotational speed and decreased with an increase in processing speed (traverse speed). The tool tilt angle had less influence on peak temperature when compared with rotational and processing speed. The hardness of the Cu/ SiC_p nano surface composite increased with a decrease in rotational speed and an increase in processing speed. Further, the hardness increased with the increase in tool tilt angle due to the effective dispersion of SiC_p particles and forging/compaction caused by stirring action during FSP (Srinivasan and Karunanithi, 2015).

In the FSP of 5052 aluminum sheets, the 5 μm and 50 nm-sized SiC particles were reinforced in to the substrate to yield an Al5052/SiC MMC. The change in the direction of the FSP tool rotation between the FSP passes, multiple passes and the associated decrease in size of SiC particles contributed to enhanced hardness and wear properties (Dolatkhah *et al.*, 2012).

The incorporation of nano-sized SiC reinforcement particles in AZ31 magnesium alloy substrate using increased tool rotational speed/advancing speed ratio produced good dispersion of nanoparticles in the Mg/SiC nanocomposite surface layer (Erfan and Kashani-Bozorg, 2011).

The Al5083/ B_4C surface composite layer (SCL) resisted wear in conformance with Archard's law which states that the volume loss in the AMC is inversely proportional to the hardness. ie, higher the hardness of the composite, lower shall be the wear rate; since the AMC shall resist the removal of material due to wear by virtue of high hardness imparted by the dispersion of nano B_4C through FSP and their good bonding with the matrix in the SCL and with the Al5083 substrate. The multiple passes of FSP enhanced the homogenous distribution of the B_4C reinforcement particles and resulted in increased hardness and formation of ultrafine grains (Yuvaraj *et al.*, 2015).

Multi-Walled Carbon Nano Tubes (MWCNT)/A1016 fabricated through FSP exhibited wettability between the hydrophilic MWCNT's and A1016 matrix. Breaking of the MWCNT occurred due to the high compressive forces prevailing during FSP. The presence of MWCNT interrupted the movement of dislocations caused due to a mismatch of elastic modulus and coefficient of thermal expansion between the aluminum matrix and MWCNT. With the increase in the volume fraction of MWCNT, the tensile strength and microhardness of MWCNT/A1016 composite increased at the cost of a reduction in elongation; which indicates that the addition of more MWCNT made the composite brittle (Liu *et al.*, 2013a).

In MWCNT/AZ31 surface composite, the dispersion of the MWCNT in the AZ31 matrix was influenced by the travel speed of the FSP tool. The uniform dispersion of the MWCNT promoted grain refinement to yield grains having less than 500 nm size. (Morisada *et al.*, 2006).

The Graphene/Aluminum surface composite was fabricated through FSP by carrying out FSP on 5052-H32 aluminum alloy sheets over which graphene oxide (GO)/water colloid was filled. Due to the frictional heat of the FSP, the GO reduced to a highly-conductive reduced GO (RGO) and thereby increasing the thermal conductivity and ductility of the MMC. (Jeon *et al.*, 2014). The strengthening mechanism in Graphene oxide (GO)/Al5083 surface composite involved grain boundaries and sub boundaries arresting dislocations and by the presence of GO or presence of reinforcing particles (Orowan theory). The mechanical properties improved, whereas the elongation reduced, which made the MMC brittle (Naghshhehkish *et al.*, 2019).

Nano Hydroxyapatite nHA/AZ31 FSPed surface composite was investigated as it has the benefits of an MMC having refined grains and embedding nHA in the magnesium alloy matrix for biomedical applications. The nHA enhances the biomineralization, wettability, corrosion resistance and thus making the FSPed MMC biocompatible. (Ratna Sunil *et al.*, 2014).

Surface Micro Composites

The FSPed surface composite (SC) formed by the addition of Al_2O_3 (AZ91/ Al_2O_3) and SiC (AZ91/SiC) to as-cast AZ91 magnesium alloy exhibited ultrafine-grained structure, good tensile strength and elongation, and improved distribution of the reinforcement particles with multiple FSP passes. The AZ91/SiC exhibited abrasive wear and delamination, whereas the AZ91/ Al_2O_3 exhibited delamination, which vanished with multiple passes of FSP. (Asadi *et al.*, 2011).

The Al1100 alloy reinforced with rice husk ash-derived, amorphous silica particles fabricated through FSP at a rotational speed of 1140 rpm, traveling speed of 45 mm/min, and a 2° tilt angle; exhibited 100% enhanced hardness. The silica particles disturbed the grain growth and caused grain refinement and reduced wear of the composite. (Zuhailawati *et al.*, 2016).

Instead of carrying out FSP on reinforcement particles filled in grooves or blind holes machined on the substrate, alternatively, the reinforcement particles can be deposited on the substrate through coating techniques. The Al_2O_3 particles of 10 μm size mixed with aluminum were coated on aluminum Al6061 substrate through cold gas dynamic spraying. The cold sprayed Al_2O_3 particles tend to segregate, which are dispersed uniformly in the MMC through FSP. The FSP of the MMC coatings decreased the reinforcement particle size, which causes a reduction in interparticle distance, i.e., the inter-particle mean free path. The reduction in inter-particle mean free path contributed to increased hardness in the MMC coating. (Hodder *et al.*, 2012). The inter-particle distance λ is expressed in the formula. (Kouzeli and Mortensen, 2002).

$$\lambda = (1 - V_p)/N_L \quad (4)$$

where

V_p is the volume fraction of the reinforcement particles and

N_L is the number of particles intercepted per unit length.

The surface composite fabricated on pure copper sheets by incorporating 25 μm SiC particles through FSP yielded a two-times increase in hardness. Further, the wear resistance and average friction coefficient were enhanced without any formation of intermetallic compounds. (Akramifard *et al.*, 2014).

The as-cast plates of AZ91 alloy subjected to FSP with the incorporation of 5 μm sized SiC particles yielded good grain refinement and enhanced hardness. The tool penetration depth (PD) greatly affected the quality of the surface composite formed through FSP. The PD is influenced by the FSP process parameters, namely traverse speed, rotational speed, and tilt angle. Generally, PD is measured as the distance from the first contact point of the tool shoulder and the workpiece surface. (Asadi *et al.*, 2010).

The fabrication of Cu/Si micro surface composites through FSP with an increase in traverse speed and a decrease in rotational speed caused a reduction in the grain size, enhanced hardness, higher average friction coefficient, and enhanced wear resistance. Whereas higher traverse speed resulted in, non-uniform distribution of SiC particles and reduction in hardness. (Barmouz *et al.*, 2011).

The fabrication of 10 μm mean diameter SiC_p particles reinforced thixoformed (TF) AZ91D alloy, surface composite layer through FSP yielded grain refinement in the nugget zone. Further grain refinement was observed in the thermomechanically affected zone (TMAZ) which is attributed mainly to dynamic recrystallization and, splitting and fracture (mechanical separation) of the primary grains. In TMAZ, strain and frictional heat increases with the increase of the number of the FSP passes (Chen *et al.*, 2010).

The Direct Friction Stir Processing (DFSP) uses a hollow-pin less DFSP tool, where the reinforcement particles flow into the enclosure between the concave tool shoulder and the substrate and get ironed into the workpiece through the rotating action of the DFSP tool. Satisfactory results were observed with just one FSP pass in the Mg/SiC_p surface composite. (Huang *et al.*, 2014).

The 5083Al alloy rolled plate surface added with micron sized SiC particles when subjected to FSP process produced surface composite layer of thickness 50–200 μm . With the incorporation of 0.7 μm average particle size of 27 vol% SiC on 5083 aluminum alloy, it was observed that as the tool traverse rate increases the bonding between the surface composite layer and the substrate is poor. (Mishra *et al.*, 2003).

As the FSP tool pin diameter is increased the diameter of the shoulder gets reduced. The shoulder being the source of frictional heat, the decrease in shoulder diameter due to an increase in pin diameter leads to the generation of less heat and formation of voids and defects in the stir zone (SZ) and clustering of SiC reinforcement particles in AA5083 alloy. The maximum temperature generated (T_{max}) in the stir zone (SZ) can be estimated by the expression

$$T_{\text{max}}/T_m = K(\omega^2/(v \times 10^4))^\alpha \quad (5)$$

Where

K is a constant having value between 0.65 and 0.75

ω is rotational speed in rpm

v is the traverse speed in inch/min

α is an exponent ranging from 0.04 to 0.06

T_m is the melting point of the alloy in $^\circ\text{C}$

The highest values of α and K yield an estimation of peak temperature. (Sharma *et al.*, 2015). Bulk surface composites could be fabricated by the dominant role of the shoulder of the FSP tool. The shoulder generates enough frictional heat to form a good bond in the SiC_p /5A06 composite layer and between the composite layer and the substrate. (Wang *et al.*, 2009).

The scattering of TiC particles during FSP of AZ31 alloy was prevented by using a pinless FSP tool which seals the top surface on the milled groove in the AZ31 alloy. The volume fraction of FSPed groove could be calculated from the expression. (Balakrishnan *et al.*, 2015).

$$\text{Volume fraction} = (\text{Area of groove}/\text{Projected area of tool pin}) \times 100 \quad (6)$$

Where,

$$\text{Area of groove} = \text{Groove width} \times \text{Groove depth} \quad (7)$$

and

$$\text{Projected area of tool pin} = \text{Pin diameter} \times \text{Pin length} \quad (8)$$

The fabrication of TiC/AA1050 surface composite through FSP was carried out on a V groove filled with TiC particles which were compressed and sealed to the V groove surface initially by a pinless FSP tool and subjected to FSP using a regular FSP tool having a pin. At low rotational speeds, insufficient frictional heat was produced which causes defects, and at high rotational speed the dilution of the TiC/Al resulted, causing a reduction in wear properties. (Akinlabi *et al.*, 2014). The AA6082/TiC surface composite exhibited enhanced wear properties and hardness attributed to the grain refinement caused by the addition of TiC particles and the FSP. The increased volume fraction of TiC reinforcement particles changes the mode of wear from adhesive wear to abrasive wear. These enhanced properties can be correlated to Archard's Law. (Thangarasu *et al.*, 2014).

The FSP of ZM21 magnesium alloy surface composite reinforced with B₄C and SiC indicated that the FSPed ZM21/B₄C surface composites are superior to the ZM21/SiC surface composite; having enhanced hardness and wear resistance. The B₄C and SiC carbide particles improve the hardness of the ZM21 surface composites through grain boundary pinning and dispersion hardening. The SiC and B₄C carbide powders change the wear behavior of ZM21 magnesium surface composite from an abrasive mode of wear to an adhesive mode of wear. (Madhusudhan Reddy *et al.*, 2013). The Cu/B₄C surface composite exhibited good distribution of the B₄C reinforcement particles and the formation of a higher area of surface composite on the Cu substrate. This was achieved with FSP parameter namely higher FSP tool rotational speed and lower processing speed which generated higher frictional heat and better material transportation associated with the increased stirring action of the FSP tool. The bonding of B₄C particles with the copper matrix and grain refinement was due to the pinning effect of the B₄C reinforcement particles. (Sathiskumar *et al.*, 2013).

Surface Hybrid Composites

The addition of CeO₂ and SiC in the Al5083 alloy matrix through FSP yielded hybrid nanocomposite possessing good grain refinement and homogeneous distribution of reinforcement particles. The Al5083/CeO₂/SiC surface hybrid composite (SHC) exhibited high wear resistance, lower friction co-efficient due to solid lubrication provided by CeO₂ particles. The wear mechanism in the Al5083 alloy was due to severe adhesive wear, whereas in the SHC it changed to abrasive wear and delamination. (Amra, Ranjbar and Hosseini, 2018). The SCs fabricated through FSP with the addition of SiC + Gr and SiC + Al₂O₃ to 6061-T6 aluminum alloy exhibited uniform distribution of the reinforcing particles in the nugget zone. The microhardness of Al-SiC/Al₂O₃ SC increased due to the presence of SiC and Al₂O₃ particles and their pinning effect. The Al-SiC/Gr SHC exhibited high wear resistance due to the presence of SiC which acts as a load-bearing element and Gr acts as a solid lubricant. Even though wear properties increased, the tensile properties decreased indicating that the material becomes brittle. (Aruri *et al.*, 2013).

The FSP of aluminum 6061-T6511 alloy with sub-micron-sized Al₂O₃ (200 nm nominal diameter) and SiC (300 nm nominal diameter) particles yielded hybrid surface composite up to 3 mm depth with the hard phases of around 20–30 vol%. The FSP resulted in a 40% reduction in friction and 90% reduction in wear, which is contributed to a high density of matrix dislocation caused by FSP. (Qu *et al.*, 2011).

The Al6063 surface hybrid composite fabricated using B₄C and SiO₂ reinforcement particles on the Al6063 substrate exhibited good grain refinement of an average grain size of 8 µm attributed to the multi-pass FSP. The combination of 30% SiO₂ and 70% B₄C to Al6063 resulted in decreased specific wear rate; whereas the SHC having 20% SiO₂ and 80% B₄C exhibited increased specific wear rate (Dinesh *et al.*, 2019).

The Al5083 SHC reinforced with multi-walled carbon nanotubes (MWCNT) and nano-sized cerium oxide particles in the volume ratio of 75–25 through FSP yielded maximum tensile strength and hardness value. The good dispersion of reinforcement particles in the nugget zone was achieved by using a threaded cylindrical hardened steel FSP tool rotating at speeds of 600 and 800 rpm and a travel speed of 35 and 45 mm/min and a 5° tilt. The incorporation of nano-sized cerium oxide increased the pitting resistance as it acts as a cathodic inhibitor. Multiple mechanisms come into play to strengthen the SHC viz., Orowan mechanism; and the existence of large coefficient of thermal expansion mismatch between the reinforcement particles and the aluminum matrix causing an increase in dislocations at the interface leading to work hardening of the matrix. Further the fragmentation and distribution of the large Al6(Mn, Fe) intermetallic particles during the multi-pass FSP process and the associated grain refinement led to enhancement of hardness due to Hall-Petch relation (Hosseini *et al.*, 2015).

The AA1050-H24 aluminum hybrid composite exhibited improved wear resistance with the addition of SiC and Al₂O₃ particles of 1.25 µm average size. The SHC was processed using an FSP tool having a square-shaped probe rotating at 1500 rpm and traveling at a speed of 1.66 mm/s. Except for the presence of some voids, the SHC had a uniform distribution of the reinforcement particles in the nugget zone. The average hardness decreased as the content of Al₂O₃ increased. The SHC having 80% SiC + 20% Al₂O₃ yielded good wear resistance (Mahmoud *et al.*, 2010).

AA6360/(TiC + B₄C) hybrid surface composite layers (SCLs) were fabricated through FSP with HCHCr steel, cylindrical threaded pin at a rotational speed of 1600 rpm, and a traverse speed of 60 mm/min and an axial thrust force of 8 kN. The FSP runs were done with two passes in opposite directions, which resulted in homogeneous distribution of TiC and B₄C particles in the AA6360 matrix. The SCLs having AA6360 50% TiC + 50% B₄C exhibited the least wear rate attributed to the fabrication of the

thin tribo film in the SCLs. The FSP enhanced the wear resistance and the strengthening mechanism enhancing the wear resistance is the combination of four processes namely, Orowan strengthening caused by the dispersion of fine reinforcement particles, strengthening due to grain refinement, quench hardening due to dislocations formed to compensate the differential thermal contraction between the matrix and the reinforcement and work hardening effect caused due to the mismatched strain between the plastic matrix and the elastic reinforcement particles. Further, the formation of oxide/tribo film from the dislodged particles acts as a solid lubricant and thus reducing the frictional coefficient and wear resistance. (Rejil *et al.*, 2012).

The wear behavior of AA6063-B₄C/TiB₂ hybrid surface improved when processed with a threaded FSP tool. The dynamically recrystallized zone (DRX) exhibited a reduction in grain size which is due to the increased dislocation density caused by the strain applied in the stir zone by the FSP tool. This grain size reduction combined with Orowan strengthening, caused by the dispersion of the reinforcement particles during FSP; improved the hardness of the MMC. The in situ formed TiB₂ particles exhibited enhanced bonding with the AA6063 matrix and contribute to the increased hardness and wear resistance. The hybrid surface composite when subjected to heat generated during wear, forms a mechanically mixed layer (MML) having a protective oxide film, like aluminum oxide or iron oxide that makes the wear become mild wear. (Narimani *et al.*, 2016).

In the hybrid metal matrix composite (HMMC) Al5083/Graphite/Al₂O_{3p}, a good distribution of reinforcement particles was observed, with the possibility of agglomeration with an increase in the volume fraction of the reinforcement particles. The HMMC having a 75% hybrid ratio (HR) of Graphite exhibited the least wear rate, whereas HMMC having 50% HR of Graphite possess good wear resistance and tensile strength. Hence the HR aids in designing the HMMC possessing the desirable properties. (Mostafapour Asl and Khandani, 2013).

The addition of carbon nanotube (CNT) and Al₂O₃ nanoparticles to the surface of Al5083 yielded a hybrid surface composite Al5083/CNT/Al₂O₃ nanocomposite. The Al₂O₃ nanoparticles got dispersed in intra-grain and grain boundaries, whereas the CNT got pinned into the grain boundaries when subjected to FSP. This behavior improved the hardness, tensile strength, and wear resistance. The presence of Al₂O₃ nanoparticles and CNT prevents the movement of dislocations and hence improves the hardness. (Ostovan *et al.*, 2020). The increased hardness conforms to the Archard equation, which states that these nanocomposites shall have better wear resistance. (Yang, 2003). The homogeneous distribution of the reinforcements leads to good interfacial bonding with the AA5083 matrix which prevents pull out during dry sliding. Further, the Al₂O₃ nanoparticles and CNT act as load barriers increases the hardness and minimizes plastic deformation. Even the damage caused to CNT during FSP, aids in the reduction of wear since the damaged CNT forms carbon films which act as a dry lubricant. (Ostovan *et al.*, 2020).

Surface-Powder Metallurgy In-Situ Composites/Intermetallic Powder Composite

The nano-sized AA7075 particles and TiC particles were packed in the groove milled on the surface of the AA7075 T651 alloy substrate. The wear rate reduction was observed. Whereas the reduction of hardness in the stir zone was observed in the T651 conditioned AA7075 alloy which losses its hardness upon plastic deformation caused by the FSP. (García-Vázquez *et al.*, 2016).

The 99% purity aluminum particles of 325 mesh size were mixed with 15% of 99.5% purity copper particles of 320 mesh size, to prepare the Al-15Cu alloy billet through the powder metallurgy route. This billet was sintered to give it sufficient strength to withstand the FSP passes. The Al-15Cu billet subjected to multiple passes of FSP formed in situ Al₂Cu intermetallic reinforcement which was distributed homogeneously in the aluminum matrix. The FSP passes and the Al₂Cu intermetallic reinforcement imparted good young's modulus, compressive strength, and compressive ductility. (Hsu *et al.*, 2005).

The Al-Cu and Al-Ti billets produced from the elemental metal powder mixtures, through powder metallurgy upon sintering get good structural strength to undergo FSP. The sintered billets undergo severe plastic deformation and the metal powders get homogeneously mixed and get a refined distribution of phases. A further exothermic reaction takes place between the aluminum and the transition metals Cu and Ti. Thus the high temperature created during the FSP and the exothermic reaction promotes the formation of intermetallic phases namely Al₂Cu and Al₃Ti, in situ during FSP. Further, the material undergoes hot consolidation to yield a fully dense material possessing high strength. The strength of the composite increased, with the increase in the content of the reinforcement. (Hsu *et al.*, 2007).

The addition of atomized aluminum powder with 10, 20, or 30 vol% denoted as Al-10Si, Al-20Si, or Al-30Si and processing through powder metallurgy route and upon sintering make the material resist the forces created during FSP. Multiple passes of FSP produced Al-Si composite led to good strength and ductility. This can be attributed to the homogeneous distribution of silicon particles and the formation of ultrafine-grained aluminum matrix. The composite displayed compressive yield strength higher than the tensile strength due to residual stress developed during FSP. The young's modulus of the composite conforms to the Halpin-Tsai equation. (Hull and Clyne, 1996). The presence of few nanosized silicon particles within the aluminum grain interacts with the dislocations moving within the aluminum grains and thus contribute to the strengthening by the Orowan mechanism. (Lee *et al.*, 2011).

The Carbon Nanotube (CNT), Al, and CNT/6061 Al powder after cold compacting when subjected to degassing and vacuum hot pressing and hot forging were subjected to multiple passes of FSP. The combined powder metallurgy processing and FSP of CNT and aluminum, CNT/Al, and CNT/6061Al produce a composite that displayed good tensile strength and electrical conductivity. During artificial aging treatment of CNT/6061 Al the Si and Mg tend to segregate at the CNT-Al interface and contributed to the increase in electrical conductivity of CNT/6061 Al; whereas the addition of CNT in CNT/Al decreased the electrical conductivity. (Liu *et al.*, 2014). The 1.5–4.5 vol% CNT/2007Al AMC produced through powder metallurgy route, yielded uniform distribution of the carbon nanotubes (CNT) when subjected to multiple overlapping FSP passes. The FSPed CNT formed good

bonding with the aluminum matrix. No carbides were formed but Al_4C_3 phase was formed at the tips of the CNTs as carbon atoms are reactive in the tips. These tips are the outcome of the shortening of the CNTs when subjected to the shear strain during FSP, but the CNTs did not lose their structural integrity and thus there is no formation of any stress concentration. The FSP dispersed the CNT in the matrix. To further improve the tensile strength and elongation, the CNTs have to be aligned by subjecting to processing like rolling. (Liu *et al.*, 2013b).

Surface Metal Powder Composites/Surface Composites SCs

The surface metal matrix composite with the inclusion of metal powders like nano Mg powder on pure zinc plate was carried out through the FSP route. The synthesized surface MMC induces grain refinement due to dynamic recrystallization and increases the hardness of the pure zinc substrate and thus making the material an ideal candidate for biodegradable orthopedic implants. The deposition of metal powder in blind holes arranged in a zig-zag formation, instead of in a groove reduces the risk of agglomeration of the metal particles during the friction stir processing (Singh *et al.*, 2019).

The fabrication of Ti6Al4V (TC4)/Zinc (Zn) surface nano composite through FSP was carried out for surface modification of TC4, to promote the osteogenic performance of the dental and orthopedic implants. The presence of Zn particles in the SC enhances the hydrophilicity thus improving the biocompatibility in terms of cell adhesion and cell proliferation. The Zn particles were filled inside holes of depth 1 mm and 0.5 mm. The FSP of TC4/Zn caused severe plastic deformation leading to the formation of numerous nanocrystalline β regions, grain boundary α phase, fine acicular martensite α' , and coarse acicular α phase. This grain refinement caused an increased surface hardness and a decreased elastic modulus in the SC. (Zhu *et al.*, 2018).

The formation of SC by the inclusion of 99.9% purity Nickel particles of 1–3 μm diameter, in A413 alloy and situ formation of Al_3Ni intermetallic particles, improved the wear behavior of the A413 alloy. The increase in the number of passes of FSP improved the distribution of the reinforcement particles and increased the intermetallic phases, which imparted wear resistance to the A413 alloy. (Golmohammadi *et al.*, 2015).

The FSP of AA7050-T7451 age-hardened alloy was carried out with the addition of hybrid particles namely Al_2O_3 , TiB_2 , Zn, and Mg. The study showed that the microhardness of the AA7050 alloy increased upon subjecting to FSP. The friction stir welding of the SC fabricated through FSP yielded an improvement in hardness. The increase in hardness of the friction stir processed SC was attributed to the material being subjected to the pass of the FSW tool which is similar to the effect produced by the multiple passes of the FSP tool. (Gangil *et al.*, 2019).

The addition of Molybdenum (Mo) to Al6082 aluminum alloy through FSP, produced SC with improved ductility. The SC exhibited a homogenous distribution of the molybdenum within the stir zone and grain refinement due to the pinning effect of the Mo particles and dynamic recrystallization. The SC improved strength without the loss of ductility, due to the good bonding of Mo particles with the Al6082 matrix and lack of interfacial reaction. (Selvakumar *et al.*, 2017).

Surface Bulk Composites

The semi-solid cast (compcast) AA2024/1 wt% Al_2O_3 nano AMC was FSPed under FSP tool rotational speed of 400 rpm and tool traverse of 20 mm/min. The FSP resulted in uniform distribution of the Al_2O_3 nano reinforcement particles, grain refinement in the AA2024 matrix, and enhanced hardness, strength, and ductility. The casting defects like porosity and shrinkage cavities were eliminated in the process of making surface nanocomposite through FSP. (Hoziefa *et al.*, 2016). The cast Al-Si alloy (A356) when FSPed yielded a microstructure with fine Si particles of size 0.25–0.42 μm . A banded structure was observed at lower tool rotational speeds/traverse speed ratios, exhibiting a low density of coarse particles in the nugget zone. The bonded structure disappeared associated with homogenous distribution of fine Si particles in the nugget zone, at higher tool rotational speeds/traverse speed ratios. (Ma *et al.*, 2006). The as-cast Al-TiC in situ composites were FSPed at a rotational speed of 1000 rpm and traverse speed of 60 mm/min to yield a defect-free stir zone having homogenized refined grained nugget zone. The mechanical properties were enhanced with the formation of dynamically recrystallized equiaxed grain structure upon subjecting to FSP. (Bauri, 2014).

Concluding Remarks

The friction stir welding (FSW) a solid-state welding technique spawned friction stir processing (FSP) a new surface engineering technique. Like friction stir welding, friction stir processing is a green technology that is aggressively researched nowadays. Conventional surface engineering techniques rely on forming a coating of protective coating which could resist wear, corrosion, etc. The friction stir processing forms a metal matrix composite (MMC) layer which becomes an integral part of the substrate metal/alloy/MMC. The virtue of imparting the properties of MMC namely high hardness, wear-resistance, and functional properties makes FSP a promising technology for a variety of applications. Currently, the FSW tool is used to execute the FSP. There is a need to customize the FSP tool to make the process scalable to widely apply in industries and real-time applications. Most of the FSP studies have been carried out on aluminum matrix composites (AMC). As magnesium-based alloys and composites are emerging in various applications there is the scope and need to study friction stir processing of these materials.

Introduction

The metal matrix composites (MMCs) are designed by considering the combined effect of metals and ceramics. Metals have moderate strength and ductility with low stiffness and low thermal stability. Whereas, ceramics are having high-temperature resistance along with high stiffness and high strength. The high strength, high modulus reinforcement particles provide an intermediate mechanical property between ductile matrix and hard reinforcement in MMCs. The MMCs with ceramic particle reinforcements demonstrate superior properties in strength, elastic properties, resistance to wear, creep and fatigue as compared to unreinforced matrix material, which makes them promising for structural application in automobile and aerospace industries.

The developed MMCs can further be exposed to various manufacturing processes such as forging, rolling or extrusion while fabrication of products for end-use applications. The manufacturability of most of these manufacturing processes highly depend on the different manufacturing process parameters like strain rate, strain and temperature (Sahoo and Panigrahi, 2019a; Zang *et al.*, 2019; Xu *et al.*, 2018b). Hence, for safe and efficient deformation of MMCs, it is important to establish the range of manufacturing process parameters like strain rate, strain and temperature etc. The ease of active defect-free deformation is called a material's workability.

The workability is defined as the ease of deformation of material for a particular metalworking process without any defect. The defects are generally in the form of shear band, local necking and surface irregularity which occurs during different types of metalworking processes. Both the material characters (such as grain morphology, second phase distribution and geometry of the sample) and process parameters (like strain, strain rate and temperature) affect the workability of materials. For cold working process, material characters are more important than the process parameters for deciding the workability because of inactive metallurgical phenomenon. However, for hot working, both the material characters as well as process parameters are important for workability.

The fundamental behavior of materials can be studied by optimizing the workability under different processing environments. Several researchers have been attempting to understand the flow behavior of materials during deformation through consequence of processing parameters (Liu *et al.*, 2019; Mokdad *et al.*, 2017; Wang *et al.*, 2016; Selvam *et al.*, 2015). They have established different maps for describing the deformation behavior and mode of fractures that arise during deformation.

Ashby developed a map by plotting the normalized shear stress against absolute temperature (Langdon and Mohamed, 1978). Fig. 1 represents a schematic diagram of an Ashby map, which is plotted by taking logarithmic of normalized stress ($\frac{\sigma}{G}$) in y axis and homologous temperature ($\frac{T}{T_m}$) in X axis. Where σ represents the stress applied, G stands for shear modulus, T signifies the temperature value, and T_m represents melting temperature of material in degrees Kelvin. The map is divided into three zones: (1) The first zone is represented by a horizontal line, ($\frac{\sigma}{G} \sim 4 \times 10^{-2}$) which signifies the material's ideal strength; (2) The second zone is at normalized stress (varies between $4 \times 10^{-3} - 4 \times 10^{-2}$) where the material deforms by the conventional motion of dislocations by means of glide through the lattice; and (3) The third zone is at stress values of $\frac{\sigma}{G} < 4 \times 10^{-3}$, where deformation behavior transform to diffusion-controlled creep processes (i.e., Nabarro-Herring diffusional creep and Coble diffusional creep).

Raj (1981) developed maps exhibiting an immense range of strain rate and temperature domains. This map is plotted by taking temperature in horizontal-axis and strain rate in vertical-axis. The boundaries in map created by Raj represent the existence of different microscopic phenomena (such as ductile fracture, adiabatic shear, dynamic recrystallization) in materials during deformation. The boundaries of temperature and strain rates are estimated by appropriate equations for these various microscopic phenomena. The areas confined through these boundaries are the domains in which the particular microscopic aspect will succeed during deformation. The map also shows a safe region which indicates the occurrence of defect-free manufacturing zone/region at certain set of processing/manufacturing parameters. Fig. 2 represent an example of Raj Map for austenitic stainless steel.

Ashby and Raj maps are valid for steady states as they have used shear strain rate equations. The equations used in Ashby and Raj maps are dependent on basic atomic mechanism such as grain boundary sliding, diffusion dislocation motion, twinning and phase transformations. The maps are valid for pure metals and cannot be applied to alloys and MMCs due to difficulties in identifying different atomistic mechanisms appropriately.

Concept of Processing Map

The hot workability of pure metals, alloys and MMCs can be analyzed by means of the processing map. A processing map is an explicit depiction of a material's response to the process parameters for finding optimum conditions for workability and to attain microstructural control in the materials. Processing map is also an important tool to design processing steps to attain maximum product yield, reproducible microstructure and mechanical properties in the material. Many material-based models have been

Fig. 1 Schematic diagram for Ashby map.

Fig. 2 Schematic diagram represents Raj map for austenitic stainless steel.

established to analyze the hot deformation behavior of the materials. The three most prominent developed models are: (1) Kinetic model, (Jonas *et al.*, 1969) (2) Atomistic model, (Raj, 1981) and (3) Dynamic materials modeling (DMM) (Prasad *et al.*, 1984).

Kinetic and atomistic models are only concisely discussed here as they form the base for the investigation of constitutive behavior; however, the processing maps will be conferred in details.

Kinetic Model

Kinetic model predicts the deformation mechanism by the help of strain hardening exponent (n) and activation energy (Q). The hot deformation mechanism is predicted by strain hardening exponent. For instance, when $n=2$ the main deformation mechanism is grain boundaries sliding. The degree of difficulty is predicted by activation energy of a material during hot working beneath certain deformation conditions.

According to the kinetic model, the steady-state flow stress can be interrelated to the temperature and strain rate over an Arrhenius equation during hot deformation (Jonas *et al.*, 1969):

$$\dot{\epsilon} = A\sigma^n e^{\frac{-Q}{RT}} \quad (1)$$

Where σ represent flow stress of materials; $\dot{\epsilon}$ signify strain rate; Q imply activation energy; A = a constant; n = stress exponent; T = temperature and R = gas constant (8.314 J/mol K).

Eq. (1) is effective for a wide range of processing parameters like temperature and strain rate for pure metals. In this case, the calculated activation energy is closely equal to the self-diffusion activation energy. However, for alloys and MMCs, Eq. (1) is effective on a narrow range of processing parameters and the estimated activation energy is exceeding than that for self-diffusion. This is due to the existence of second phase, solid solution or dispersion hardening in alloys and hard reinforcement in MMCs which often generate back stress during deformation. This complicates the evolution of rate-controlling deformation mechanisms in alloys and MMC materials. During hot deformation, the changes in the microstructure such as grain size, are usually interrelated through Zener-Hollomon parameter, Z , which is expressed as per Eq. (2) (Selvam *et al.*, 2015):

$$Z = \dot{\epsilon} e^{\frac{Q}{RT}} \quad (2)$$

In pure metals, the relation between average grain diameter and Z on a log scale is an inverse linear correlation. The limitation of the kinetic model is that it does not help in the microstructural control or optimization of the workability of commercial materials or the avoidance of defects in processing.

Atomistic Model-Raj Map

Atomistic model predicts the different mechanisms involved in the following three types of microstructural damage during hot working (Raj, 1981):

- (1) *Microstructural defect in the form of voids*: Conventional dimple type defects in ductile materials during deformation at moderate strain rate and low temperature which occurs due to void formation at the interface of hard particles and matrix;
- (2) *Wedge crack development*: Primary reason is due to grain boundary sliding action at grain boundary triple junctions, which dominates at higher temperatures and lower strain rates; and
- (3) *Adiabatic shear band creation*: Happens at very high strain rates and lower temperatures.

The equations used to stipulate the boundaries are obtained from suitable phenomenological and Raj models and the safe zones to prevent the above three damage causing processes (i.e., microstructural defect, wedge cracking, shear band creation) are established accordingly. Within this regime, excellent hot workability is obtained without causing any microstructure defects through the mechanism of dynamic recovery (DR) at lower temperatures and dynamic recrystallization (DRX) at higher temperature.

The validity of the Raj model is limited to dilute alloys and pure metals. However, for complex alloys and MMCs this model validity is undefined. In addition to this, different variety of experimental data are essential in order to plot the map. The different zone in the Raj map are dependent on the assumptions made concerning the microstructural properties. For instance, the cavitation domain zone would depend on the assumption of second phase particles and its distribution.

Dynamic Materials Modeling (DMM)-Processing Map

This model is based on the concepts of irreversible thermodynamics, modeling of physical systems, large scale study of plastic flow by continuum mechanics, deterministic disorder, and non-linear dynamics and hence it is extremely interdisciplinary (Rao and Prasad, 2014).

According to this model, the workpiece material dissipates power during high temperature deformation in two corresponding ways:

- (1) In the form of heat or temperature rise and
- (2) In the form of microstructural variation.

The hot workability of the specimen mainly depends on the power dissipation due to microstructural variation and should be evaluated explicitly. The dynamic constitutive equation used for hot workability/high-temperature deformation behavior of materials is as follows (Prasad *et al.*, 1984):

Fig. 3 Schematic figure of (a) G content and J co-content explanation and (b) $J_{\max}$ which occurs at $m = 1$.

$$\sigma = K\dot{\epsilon}^m \quad (3)$$

where σ represents stress, K is a constant, m stands for strain rate sensitivity, $\dot{\epsilon}$ represents applied strain rate.

Fig. 3(a) represents the schematic diagram for representing the constitutive equation which signifies the stress-strain rate behavior of a material obtained through the applied stress at a constant temperature and strain. At different applied strain rates, the path of the curve will be different. For instance, at lower strain rate, the material may experience a large plastic flow before failure and the material may undergo quick fracture with less plastic deformation at faster strain rates. The total power dissipated (P) is expressed as two corresponding functions given as (Prasad *et al.*, 1984):

$$P = \sigma \dot{\epsilon} \int_0^{\dot{\epsilon}} \sigma d\dot{\epsilon} + \int_0^{\sigma} \dot{\epsilon} d\sigma = G + J \quad (4)$$

The first integral function is termed as “G content” which indicates the key input power for plastic deformation and deformation heating. The second integral term is “J co-content” which represents the energy that microstructural changes dissipate.

The strain rate sensitivity (m) is found by means of differentiating the power between deformation heat and microstructural changes of flow stress.

$$\frac{dJ}{dG} = \frac{\partial P}{\partial G} \frac{\partial J}{\partial P} = \frac{\dot{\epsilon} d\sigma}{\sigma d\dot{\epsilon}} = \frac{\partial(\ln \sigma)}{\partial(\ln \dot{\epsilon})} = m \quad (5)$$

The J co-content can be obtained by substituting Eq. (3) in Eq. (4), we get:

$$J = \int_0^{\sigma} \dot{\epsilon} d\sigma = \frac{m}{m+1} \sigma \cdot \dot{\epsilon}^m \quad (6)$$

The J co-content value attains its maximum limit ($J_{\max}$) when strain rate sensitivity (m) = 1, and the workpiece acts as a linear dissipator; thus,

$$J_{\max} = \frac{\sigma \cdot \dot{\epsilon}}{2} \quad (7)$$

Fig. 3(b) representing schematic figure for stress-strain rate behavior of a material when $m = 1$. In this case, one-half of the power is exhausted by means of material flow and the other half is dissipated as heat.

The power dissipation efficiency (η) is obtained by considering ratio between power dissipated to the maximum power dissipation via microstructural revolution and is expressed as (Prasad *et al.*, 1984);

$$\eta = \frac{J}{J_{\max}} = \frac{m\sigma\dot{\epsilon}/m+1}{\sigma\dot{\epsilon}/2} = \frac{2m}{m+1} \quad (8)$$

Power dissipation and instability maps

The power dissipation or stability map is developed by using the values of power dissipation efficiencies (η) and plotted on $\log \dot{\epsilon}$ in Y-axis vs Temperature in X-axis. However, only partial information about the hot deformation is carried by the power dissipation map. The power dissipation map only gives information regarding the microstructure efficiency but unable to explain any instruction related to the instability of the hot deformation process. The instability maps describe the zone of instability and the unwanted deviations in the microstructural aspect (such as intergranular cracking, edge cracking etc.). These instability zones in the processing map are not safe and should be evaded during the hot deformation processing.

The criterion for instability is proposed by Prasad and Seshacharyulu. The criterion can be represented by the following relation when instability occurs (Prasad and Seshacharyulu, 1998):

$$\frac{\partial D}{\partial R} < \frac{D}{R} \quad (9)$$

where D represents dissipative function and R signifies the parameter related to strain rate. D can be replaced with J , the “co-content” in order to consider the microstructural dissipation, and the resultant equation for flow instability related by microstructure is expressed as per the following equation (Jonas *et al.*, 1969):

$$\xi(\dot{\epsilon}) = \frac{\partial \ln[m/(m+1)]}{\partial \ln \dot{\epsilon}} + m < 0 \quad (10)$$

The dimensionless parameter ξ can be calculated through Eq. (10) which is a function of deformation temperature and strain rate. The region with negative ξ values in processing map signifies flow instabilities. Flow instability microstructures demonstrate the presence of localized flow, adiabatic shear bands and wedge cracking (Son *et al.*, 2018).

Development of Processing Map

High precision experimental value on flow stress is required for the development of processing maps at different processing constraints such as strain rate and temperature. In order to construct processing maps, the processing parameters have to be selected by considering real life manufacturing simulations for hot workability such as: the preferred temperature ranges (generally from 0.65 to 0.85 T/T_m) and the range of strain rate (usually varies from 0.0003 to 100 s^{-1}).

The following requirements/assumptions are often made while developing the processing maps as per this modeling approach:

- (1) A constant true strain rate is preferred than nominal strain rate,
- (2) The temperature distribution should be uniform throughout the test material, and
- (3) The rise in temperature during deformation should be measured to get the actual flow stress.

For achieving the constant true strain, isothermal hot compression testing is a suitable process. A standard cylindrical specimen with L/D ratio in the range of 1.2–1.5 is generally used to conduct compression tests. In order to maintain the isothermal conditions, the platens, push-pull rods and specimens have to be heated together inside the furnace. While deforming at ambient temperatures, (1) appropriate lubricant (such as graphite, MoS₂, or molten glass) should be used to reduce friction between the specimen and the holder and (2) applied deformation strain (true strain) should be within the threshold range (~ 0.7 – 1.0%) to avoid barrelling effect. After compression testing, the elastic portion should be subtracted from load vs. stroke length data for the machine compliance correction and then these data should be transformed into true stress-true strain curves as per the following equations (Zhong *et al.*, 2014):

$$\text{True stress } (\dot{\sigma}) = \frac{F}{A_0(1 - \epsilon)} \quad (11)$$

$$\text{True strain } (\dot{\epsilon}) = \ln(l_0 - l) \quad (12)$$

Where F represents the load applied during deformation, ϵ signifies engineering strain, A_0 indicates original area of cross-section of the sample, l_0 = original height of the sample and l = instantaneous height.

Similarly, the flow stress information at various strain levels are obtained at different range of three process parameters such as strain rates, strains and temperatures. There may be increase in temperature at high strain rates (above 1 s^{-1}). It is required to incorporate the suitable correction factors in the flow stress values at such strain rate level of loading conditions. The corrected flow stress versus temperature and strain rate are generally being used as input to generate processing maps at various strain levels.

The first step for obtaining a processing map is to calculate strain rate sensitivity (m). For this, the log (flow stress) vs log (strain rate) curve is drawn and then fitted by using a spline function. The value of m is dependent on strain rate and is calculated at distinct processing temperatures. Then the efficiency of power dissipation (η) is estimated as per Eq. (8). The obtained η value is a function of deformation strain rate and temperature and is used to draw the contour map in temperature vs log (strain rate) frame, that establishes the power dissipation map (Fig. 4(a)). The instability map is plotted using m values that help to determine the instability parameters (Eq. (8)) (Fig. 4(b)). The boundaries for power dissipation map and instabilities are superimposed to obtain the processing map (Fig. 4(c)).

Mechanisms of Processing Map for Metal Matrix Composites

The processing map for MMC material consists of different zones namely stable or safe and instable or unsafe zone. The deformation mechanisms responsible for safe and unsafe zones in different MMCs are explained in this section.

Stable Zone

The stable zone of a processing map signifies the safe workability region of material without the formation of any defect. In this zone, the deformation mechanism is mainly dominated by dynamic recovery (DR), dynamic recrystallization (DRX), and super plasticity (Rao and Prasad, 2014). However, the occurrence of DRX is more efficient than that of DR during hot deformation as DRX provides softening along with microstructural reconstruction.

Dynamic recrystallization (DRX)

In this process, recrystallized grains are simultaneously formed during deformation by both nucleation and growth processes. In MMC materials, the presence of hard reinforcement plays a significant role in nucleation and growth of these DRX grains more

Fig. 4 Schematic diagram for (a) power dissipation map (b) instability map and (c) processing map.

prominently than unreinforced alloys. The tendency for occurrence of DR and DRX can also be observed indirectly by flow stress response (decrease in flow stress indicates the existence of DR and DRX) and directly by detailed microstructural characterization (EBSD, TEM, SEM, Optical, etc).

The processes of DRX can be described in two ways (a) continuous DRX and (b) discontinuous DRX. In continuous DRX, the nucleation of new grains form homogeneously all over the materials and the growth of these grains are rare. In contrast, discontinuous DRX involves both nucleation and irregular growth of new grains. Continuous DRX can be termed as a single-step deformation process whereas discontinuous DRX is known as double-step process.

The misorientation of grain boundary is also a key factor for DRX nucleation. The dislocations get accumulated at the vicinity of grain boundaries and form substructures near them. Further, the formed substructure is engrossed by dislocations near it and progressively shielded by low angle grain boundaries (LAGBs). When there is a transformation of LAGBs to high angle grain boundaries (HAGBs), re-crystallized grains nucleate. This propensity of the recrystallization method is identified as continuous DRX.

Fig. 5 shows the EBSD micrograph of a stable zone for a solution treated AZ91 magnesium alloy (base) and AZ91/TiC + TiB₂ (composite) magnesium matrix in-situ composite (Sahoo and Panigrahi, 2019a). The microstructure consists of two types of DRX grains (1) partially developed discontinuous DRX grains (**Fig. 5(a)**) in the base material and (2) a full-grown equiaxed continuous DRX grains (**Fig. 5(b)**) in the composite material. The difference in morphology of DRX grains is due to variation in dislocation generation as there is an existence of coefficient of thermal expansion (CTE) discrepancy between matrix and in-situ reinforcement. Further, these dislocation motions are hindered by in-situ reinforcement during deformation which caused a supplementary pile-up of dislocations in the material. Because of this, more activation energy is required for occurrence of DRX in the composite material as compared to the base material. The fraction of LGBs are found to be 10.3% and 8.7% for base and composite material respectively (**Fig. 5**). Therefore, composite material contains more continuous DRXs grains as compared to the base material.

Compd.* 776, 865–882. doi:10.1016/j.jallcom.2018.10.276 with permission from Elsevier.

Dynamic recovery (DR)

Besides DRX, the other deformation mechanism in stable zone is dynamic recovery which usually happens at lower strain rates and temperatures. This domain is observed in the hot working of materials where workability is usually limited compared to that in DRX domain. This mechanism also relies on the SFE of the material and occurs mainly on high SFE materials such as aluminum.

One such DR dominated microstructure of a hot deformed MMCs (ZK60 Mg matrix reinforced with Al₁₈B₄O₃₃ and 2024 Al matrix reinforced with ZrB₂) are shown in Fig. 6. The presence of low dislocation density and more fraction of subgrains are the signature of DR dominated microstructure. Further, these sub grain boundaries formed due to DR is gradually transformed into new high angle grain boundaries at large strains (Wang *et al.*, 2008).

Superplastic deformation

The 3rd mechanism that occurs during stable zone deformation is super-plasticity. This domain pops up at a low strain rate and high temperature, where the dominant mechanism is the viscous process of grain boundary sliding. Grain boundary sliding mechanism generally occurs in materials with smaller and equiaxed grains (< 10 μm). The superplastic domain is not a completely “safe” zone except during deformation processing the state of stress is controlled. There is a high chance for cavitation and wedge-cracking during superplastic deformation.

Instable Zone

The different mechanisms responsible in the instability zone of processing map is wedge cracking, localized plastic flow and adiabatic shear bands.

Wedge cracking

Wedge cracking mainly appears when the deformation temperatures are high and strain rates are low (Ramanathan *et al.*, 2006). At such deformation domain (high temperature and low strain rate), superplastic deformation via grain boundary sliding is dominant. Because of the presence of grain boundary sliding, stress concentration arises at the triple junctions of grain boundary. If this stress concentration is not relieved by the strain accommodation process quickly, then wedge cracking occurs.

Fig. 7 represents the SEM microstructure of Al6063 + (Al₂O₃ + Y₂O₃) nano-composite which exhibited wedge cracking during deformation at T = 400°C and $\dot{\epsilon}$ = 0.1 s⁻¹.

Fig. 7 SEM micrograph displaying wedge cracking at $T = 400^\circ\text{C}$ and $\dot{\epsilon} = 0.01\text{ s}^{-1}$. Reproduced from Ahamed, H., Senthilkumar, V., 2012. Hot deformation behavior of mechanically alloyed Al6063/0.75Al₂O₃/0.75Y₂O₃ nano-composite – A study using constitutive modeling and processing map. *Mater. Sci. Eng. A* 539, 349–359. doi:10.1016/j.msea.2012.01.109 with permission from Elsevier.

In addition to wedge cracking, the deformation mechanism in instability zone comprise formation of void at hard particles (ductile fracture), inter-crystalline cracking or hot shortness (at high temperatures and high strain rates value), and cracking along the prior particle boundaries (only in the case of P/M billets). Along with these mechanisms, the microstructure characteristic can also be hampered through deformation because of the formation of flow instabilities, which is illustrated in different ways such as: flow localization, dynamic strain aging, adiabatic shear band development and flow rotation.

When a MMC deforms at low temperature and high strain rate, the presence of hard particles in the soft matrix results in large accumulated stresses due to gradient in plasticity between matrix and reinforcement, which leads to crack and debonding at the matrix-reinforcement interface along with microstructural damage because of cavity formation. This results in poor ductility and

Fig. 8 SEM micrograph showing (a) void formation at $T = 350^{\circ}\text{C}$ and $\dot{\epsilon} = 0.1 \text{ s}^{-1}$, and (b) matrix cracking and pores at $T = 500^{\circ}\text{C}$ and $\dot{\epsilon} = 0.1 \text{ s}^{-1}$ in the nano-composite. Reproduced from Ahamed, H., Senthilkumar, V., 2012. Hot deformation behavior of mechanically alloyed $\text{Al6063}/0.75\text{Al}_2\text{O}_3/0.75\text{Y}_2\text{O}_3$ nano-composite – A study using constitutive modeling and processing map. *Mater. Sci. Eng. A.* 539, 349–359. doi:10.1016/j.msea.2012.01.109 with permission from Elsevier.

inferior workability of MMCs. **Fig. 8(a)** represents SEM micrograph of nano Al MMC material deformed at $T = 350^{\circ}\text{C}$ and $\dot{\epsilon} = 0.1 \text{ s}^{-1}$ which represents void formation in the nano-composite.

Deformation at high temperature and high strain rate in MMCs develop cracks and pores in the matrix and matrix/reinforcement interface. At high temperatures, the matrix of MMC becomes soft. When the soft matrix undergoes high strain rate deformation, flow stress suddenly increases due to the lack of deformation time and particle reinforcement mismatch. When the local flow stress exceeds the fracture stress, crack initiates mainly at the particle/matrix interphase followed by crack growth upon further loading. Hence, this region in processing map is not appropriate for bulk metal processing and this should be avoided. **Fig. 8(b)** represents similar kind of microstructure which shows cracks and pores deformed at $T = 500^{\circ}\text{C}$ and $\dot{\epsilon} = 0.1 \text{ s}^{-1}$ of nano Al MMC material.

Network structure in MMC also plays a significant role in deciding the workability of materials. **Fig. 9** shows network structured TiBw particle reinforced Ti6Al4V composites with instable deformation features. The debonding between the hard TiB particles and a soft matrix is observed in the network boundary (**Fig. 9(a)**). This is due to the inconsistent deformation between the reinforcement (TiBw particles) – matrix interface at a high strain rate (10 s^{-1}). Also, the presence of flow localization bands can be observed in **Fig. 9(b)** which represents excessively elongated α grains in the compressed matrix zone. The presence of the flow localization bands is due to the low thermal conductivity of Ti6Al4V matrix. Furthermore, the presence of network structure in MMC is possibly detrimental to heat conduction at high strain rates.

Processing Map of Metal Matrix Composite

The MMCs contain different types of both reinforcements and matrices which influence their hot deformation behavior and hence significantly influence their processing maps. Several researchers have developed processing maps for (1) Al-based MMCs, (2) Mg-based MMCs and (3) Ti-based MMCs. They established the mechanisms behind the difference of the workability of these MMCs as compared to unreinforced counterpart alloy.

Aluminum Metal Matrix Composite

Aluminum metal matrix composites (AMMCs) are extensively used in the aerospace and automobile industry for their lightweight, high specific stiffness, strength to weight ratio, good formability and high-temperature resistance (Jaseem *et al.*, 2018). Being Al as matrix material, the crystal structure of AMMCs is FCC which has 12 number of slip systems. In order to have proper deformation, at least 5 independent slip systems are essential. Due to sufficient number of slip systems, AMMCs show a reasonable ductility with combination of strength at room temperature. During hot deformation processing, these AMMCs are affected by different processing parameters such as strain rates and temperatures. Many researchers have been investigating the safe workability limit of these developed AMMCs by processing maps.

Addition of reinforcement makes a reasonable improvement in hot workability limit of Al alloys. **Fig. 10** shows the comparison of processing map for Al 7075 alloy (Rajamuthamilselvan and Ramanathan, 2011) and Al 7075 + SiC composite (Rajamuthamilselvan *et al.*, 2010). The optimum workability limits for base alloy is at temperature and strain rate of 350°C and 0.1 s^{-1}

Hot deformation behavior of 7075 alloy. *J. Alloy. Compd.* 509, 948–952. doi:10.1016/j.jallcom.2010.09.139. Rajamuthamilselan, M., Ramanathan, S., Karthikeyan, R., 2010. Processing map for hot working of SiCp/7075 Al composites. *Trans. Nonferr. Met. Soc. China* 20, 668–674. doi:10.1016/S1003-6326(09)60196-5 with permission from Elsevier.

respectively with power dissipation efficiency (η) of 28%. The workability range of its composite has increased to temperature range of about 380–440°C and strain rate range of 0.1–0.9 s⁻¹ with the η value varies from 26%–30%.

According to Fig. 10, the deformation temperature for workability domain of Al 7075-SiC composite has increased by about 50°C as compared to its unreinforced counterpart with a comparative reduction in the flow instability regime. The improvement in workability temperature is basically due to presence of SiC particles which provides a back stress during deformation.

The deformation strain has also influenced the processing map of AMMCs. Fig. 11 demonstrates the processing maps for Al2024 + ZrB₂ composite at different strains of 0.2, 0.4, 0.6 and 0.8 (Kai *et al.*, 2015). The stable zone area of processing map, is represented by green color shadow and that of instable zone is marked in red color shadow. The power dissipation efficiency (η) value is found to be less than 30% for strain of 0.2 and 0.4, whereas η value is greater than 30% at strain of 0.6 and 0.8. The instability region also increases with increase in strain. Table 1 represents the optimum workability conditions for processing map of different AMMCs.

From Table 1 it can be seen that the optimum conditions for workability of AMMCs depend on size, volume fraction and types of reinforcement. Most of the processing maps comprise of two stable zones. The processing parameters for 1st stable zone varies from 350 to 440°C and at a strain rate of 0.001–0.1 s⁻¹. The 2nd stable zone occurs at higher temperatures varying from 440 to 475°C and strain rate of 0.03–1.0 s⁻¹. The deformation mechanism of stable zone is same as discussed in Section “Stable Zone”

i.e., it consists of DR, DRX and superplastic deformation mechanism. Al being a high stacking fault energy material, the deformation mechanism at elevated temperature is DR. As the 1st stable zone is at low temperature and high strain rate, DR is main softening mechanism in this zone (Fig. 6(b)). Deformation in zone 2 (i.e., at high temperature and low strain rate) leads to mostly dynamic recovery in matrix and dynamic recrystallization at particle or reinforcement/matrix interface. At higher temperatures and slow strain rates, the fraction of low angle grain boundaries (LAGBs) (49.4%) were reduced drastically and high angle grain boundaries (HAGBs) (50.6%) were increased. In this zone, the LAGBs were rearranged due to the dynamic recovery and transferred into the HAGBs. Due to this transformation of LAGBs to HAGBs, DRX mostly occurs during deformation.

Magnesium Matrix Metal Matrix Composite

Magnesium metal matrix composites (MMMCs) have fascinated widespread attention for their promising applications in aerospace, automotive and defense industries due to their low density, high specific strength and stiffness (Sahoo and Panigrahi, 2019b, 2018b; Sahoo et al., 2018; Sahoo and Panigrahi, 2018a). However, the addition of hard brittle ceramic particles and hexagonal closed packed crystal structure of magnesium matrix limits their plastic deformability at room and low temperatures. Therefore, the MMCs are generally deformed at high temperatures in order to activate additional slip systems during deformation.

Addition of reinforcement makes additional improvement in deformation behavior at elevated temperature of Mg alloys. Fig. 12 shows the comparison between processing map of AZ91 Mg base alloy and AZ91/(TiC + TiB₂) Mg in-situ composite (Sahoo and Panigrahi, 2019a). Due to presence of in-situ TiC + TiB₂ reinforcement, the power dissipation efficiency (η) increases from 0.46 (base alloy) to 0.53 (in-situ composite).

The processing map of MMCs is also sensitive to strain. Fig. 13 demonstrates the processing maps for AZ91 + bimodal size SiC composite at different strains of 0.3, 0.4 and 0.5 (Zhou et al., 2014). In the processing map, the stable zone area is larger at strain 0.3 as compared to other strains (i.e., at strain 0.4 and 0.5). The power dissipation efficiency (η) value of stable zone at strain 0.3 is also found to be higher than other strain conditions. The η value in stable zone at strain 0.3 is found to be 44%, which appears in the lower strain rate and at the temperature range of 370–420°C (Fig. 13(a)). However, in the case of higher strains of 0.4 and 0.5 (Fig. 13(b) and (c)), the η value appears at temperature range of 270–370°C. In addition, the power dissipation efficiency (η) value increases with increasing strain from 0.3 to 0.5 at lower temperature range (270–370°C) whereas at high temperature range (370–420°C) the value of η decreases with increasing strain. The instability region also increases with increase in strain.

The size of reinforcement also plays an important role in deciding the workability limit of processing map. Fig. 14 represents the comparison between stable zone and instable zone of AZ91 alloy, micro-SiC + AZ91 composite and nano-SiC + AZ91 composite. From the figure, it can be concluded that the stable zone area of nanocomposite is broad as compared to micro-composite and base alloy (Fig. 14(a)). The instability zone comparison of the three materials is represented in Fig. 14(b) and there is no instability zone for AZ91 alloy as it appears at a comparatively high strain rate ($> 1.0 \text{ s}^{-1}$), which is beyond the range shown. The presence of micron and nano-size SiC particles extend the area of the instability zone of the matrix to a lower strain rate and even higher temperature.

Table 2 represents optimum parameters for processing map on Mg MMC.

From the Table 2 it can be seen that the optimum processing condition for obtaining best workability of most of the MMCs are mostly having three zones (Zone-I, Zone-II and Zone III). The temperature range in Zone-I, Zone-II and Zone-III mostly varies

Fig. 13 Processing maps of the AZ91 + SiC composite at the strains of (a) 0.3, (b) 0.4 and (c) 0.5. Reproduced from Zhou, S.S., Deng, K.K., Li, J.C., *et al.*, 2014. Hot deformation behavior and workability characteristics of bimodal size SiCp/AZ91 magnesium matrix composite with processing map. *Mater. Des.* 64, 177–184. doi:10.1016/j.matdes.2014.07.039 with permission from Elsevier.

in the temperature range of 250–350 $^{\circ}\text{C}$, 350–410 $^{\circ}\text{C}$ and 410–490 $^{\circ}\text{C}$ respectively. In order to understand the influence of different temperature on hot deformation mechanism of MMCs, it is important to understand the different deformation mode in Mg alloy/MMCs. There are four possible deformation occurs in Mg and its alloys (Panigrahi *et al.*, 2011): (1) basal slip, i.e., slip on the (0001) plane with a $\langle 11\bar{2}0 \rangle$ Burgers vector, (2) prismatic slip ($10\bar{1}0$) $\langle 11\bar{2}0 \rangle$, (3) first-order pyramidal slip type ($10\bar{1}1$) $\langle 11\bar{2}0 \rangle$ and (4) second-order pyramidal slip ($c + a$) type-II ($211\bar{2}$) $\langle \bar{2}113 \rangle$. Activation of these slip systems depend on their CRSS value. The CRSS of above-mentioned four slip systems are in the ratio of 1:30:50:100 at room temperature. Basal slip and prismatic slip get activated during deformation at room temperature and low temperature respectively where as second order pyramidal slip system get activated above 400 $^{\circ}\text{C}$.

Magnesium is a high stacking fault energy (SFE) material, alike to those of aluminum (Ion *et al.*, 1982) and therefore, during high temperature deformation, MMCs might be expected to soften by dynamic recovery rather than dynamic recrystallization. However, most of the stable zone in MMCs shows the presence of dynamic recrystallization during the deformation at high temperature (Fig. 5). This is due to the deficiency of slip systems in magnesium rather than to the effect of SFE. As the 1st stable zone is at low temperature, basal slip is the easiest mode to activate during deformation. However, there are only two independent slip systems in basal slip, which still does not provide the five independent slip systems which is essential for homogeneous deformation of a polycrystalline material. To fulfill this condition, an additional twin system is activated during low temperature deformation. The temperature in Zone II and III is favorable for activation $c + a$ dislocation of the second-order pyramidal system. Also, cross-slip occurs in pyramidal slip systems that significantly contribute to the restoration of the DRX nucleus. Since many pyramid systems are involved, the nucleation rate will be faster than the grain boundary displacement. DRX will therefore be controlled by migration rates, depending on the self-diffusion.

Titanium Matrix Metal Matrix Composite

Ti alloys exhibit high specific strength, excellent high-temperature strength which make them potential candidate for variety of structural components in aerospace, high temperature appliances and medical sectors. The addition of ceramic reinforcement can further enhance mechanical properties of Ti alloys. Few researchers have studied the high-temperature behavior of titanium matrix metal matrix composites (TMMCs) through processing map and established their deformation mechanisms.

The addition of ceramic reinforcement to Ti alloy affects the stable zone of processing map. Fig. 15 represents the processing map for Ti–1.5Fe–2.25Mo–0.6Y alloy and Ti–1.5Fe–2.25Mo–0.6Y + 10% Mo₂C composite (Liu *et al.*, 2010b). The area under stable zone is found to be more in alloy as compared to composite. This is due to large difference in elastic modulus between matrix and reinforcement which resulted void formation during deformation in composite. Table 3 represents the processing map details of the published literature on TMMCs.

As per Table 3, the optimum processing condition for obtaining best workability of most of the TMMCs are generally varying between 900–980°C. This optimum workability range (900–980°C) of TMMCs is higher than that of AMMC and MMC materials. The crystal

04	Ti-6Al-6V-2Sn + 12 vol% of TiC	650–950°C, 0.015–15 s ⁻¹	800–950°C & 0.1 s ⁻¹	Poletti <i>et al.</i> (2008)

structure of Ti alloy at room temperature and pressure is hexagonal close-packed (HCP) α phase through a c/a ratio of 1.587. The Ti alloy experiences an allotropic conversion to a body-centered cubic (BCC) β phase at about 890°C, which remains stable up to the melting temperature. Due to BCC crystal structure, it is easy to deform the Ti alloy in this zone as compared to α phase which is HCP structure. Therefore, all the stable zone falls in the range of 900–980°C. The number of literatures on high-temperature behavior study of TMMCs is comparatively lesser than AMMCs and MMMCs due to difficulty in processing of TMMCs at high temperature domain.

Conclusion

The hot workability of metal matrix composites (MMCs) necessitates a systematic understanding of their constitutive behavior during hot working deformation domain. This is usually done by modeling the MMCs during hot working deformation behavior with objectives of establishing the conditions for optimal workability safe processing domain and for evading micro and macro defects in the material. Though kinetic and atomistic models have been developed over the years, the more appropriate and recent model for MMCs is based on illustrating the dynamic material behavior by means of processing maps.

The processing map of MMCs establishes their safe/stable and unsafe/instable hot working processing zones. The main deformation mechanism for stable zone is dynamic recrystallization (DRX), dynamic recovery (DR) and superplasticity. Whereas, wedge cracking, pores, cavitation are the dominant deformation mechanisms in instable zones.

In aluminum metal matrix composite (AMMC) both DR and DRX are the primary deformation mechanisms of the stable zone. Since aluminum is having high stacking fault energy (SFE), the deformation mechanism is DR based at low temperature and DRX based at high temperature. This is due to transformation of low angle grain boundaries to high angle grain boundaries during deformation at high temperature.

In magnesium metal matrix composite (MMMC), deformation occurs through DRX. At high temperature many pyramid systems are involved during deformation and hence the nucleation rate will be faster than the grain boundary displacement. DRX will therefore be controlled by migration rates, depending on the self-diffusion of MMMCs.

The stable zone in titanium metal matrix composite (TMMCs) falls in the range of 900–980°C. This is due to the Ti alloy experiences an allotropic conversion to a body-centered cubic (BCC) β phase at about 890°C, which remains stable up to the melting temperature. Due to BCC crystal structure, it is easy to deform the Ti alloy in this zone as compared to α phase which is HCP structure.

In conclusion, the processing map technique has proven to be an influential tool to expose the optimum conditions for hot workability domain by appraise process parameters and to accomplish microstructural control in the MMCs material.

Introduction

Metal matrix composites consist of two parts, a matrix which is a metal and the embedded reinforcement could be an organic constituent, ceramic, metallic or any other material. The properties of composite materials are tailored such that it is greater than the properties of the individual materials. For the past few decades this has been a major source of interest for many scientific researchers, which finds applications in aerospace, automobiles, sporting goods etc. Several journal articles and proceedings have been published depicting the advanced applications of these materials by developing their machining, electronic, tribological, physical, mechanical, optical properties, etc. Due to the unlimited possibilities in designing these composites by combining various materials, they could possibly replace several conventional materials in the near future.

In principle, any two or more materials can be combined to form a composite (Ashby, 2001). Composites can be synthesized using a number of material classes like metals, ceramics, glasses, elastomers and polymers (Ashby, 2001). Understanding these materials requires fundamental knowledge of its structure, property, processing and performance – the concept of materials science tetrahedron. Their microstructures are different as compared to metals and alloys, due to the interaction between different constituents (e.g., metal-ceramic) and the presence of interfaces.

Generalities About the Composites

Depending on the type of matrix (organic, metallic and ceramic), the first basis of classification is the binder, which is generally a soft phase. Organic can be classified into polymer-based and carbon-carbon type. Fiber reinforced glasses (FRG) and intermetallic compound matrix composites (IMC) are other classifications of composites (Bauri *et al.*, 2018).

Types and characteristics of MMCs

Staab (1999) classified MMCs into three categories depending on their solubility and interaction between the matrix and reinforcements. Al_2O_3 in Cu MMCs (Rajkovic *et al.*, 2014) belonged to Class I type (Staab, 1999) where there is no interaction between these constituents as they are insoluble. Partial solubility and interaction over a period of time is observed for W/Cu type MMCs, which was categorized to Class II (Staab, 1999). SiC in Al MMCs (Basak *et al.*, 2019) was categorized to Class III type where manufacturing issues take place that can be treated via optimum control in processing (Staab, 1999). In general, MMCs have high thermal conductivity (Qu *et al.*, 2011), electrical conductivity (Zuo *et al.*, 2020), strength (Russell *et al.*, 1999), fracture toughness (Mileiko *et al.*, 2020), wear resistance as compared to other materials. Several Al, Ti, Ni and Cu based MMCs are used for high performance applications (Pandey *et al.*, 2010). Addition of boron nitride to Cu based MMCs was studied by Chen *et al.* (2020b) to enhance the tribological behavior of brake-pad/disc friction pairs in high-speed trains. Shabadi *et al.* (2015) studied the thermal conductivity behavior of yttria reinforced copper. Friction stir processing was used to synthesize these composites for functional applications and with yttria addition, the coefficient of thermal expansion reduced due to a modified microstructure.

Materials

Matrix

The matrix in MMCs can be either a metal or an alloy. Among MMCs, several types exist, most commonly aluminum, magnesium, copper, nickel, nickel aluminides and titanium. Aluminum based MMCs are typically used to manufacture brake parts and engine pistons. Magnesium based MMCs are used today for biomedical applications (Bommala *et al.*, 2019). Al and Mg MMCs are the most commonly used matrices for requirements such as specific strength. With respect to its microstructure, factors such as residual stress, chemical composition, grain size, texture, defects are significant to determine its characteristics (Dermarkar *et al.*, 2006).

Reinforcements

There are several types of reinforcements (or fillers) available, such as ceramic (borides, carbides, nitrides, oxides) (Shuvho *et al.*, 2020), metal (Madhusudan *et al.*, 2016), metallic glass (Wang *et al.*, 2014b), intermetallic (Chaubey *et al.*, 2012), carbon-based (Xavior and Kumar, 2017), refractory metals (Yuan *et al.*, 2020), semiconductor, non-conventional such as egg-shell, ash or a combination of these materials depending upon the desired property such as strength, ductility, elastic modulus, density, thermal stability, compatibility with the matrix, electrical conductivity, etc. for end application. Metal matrix composites w.r.t the reinforcements can be classified into particulates (Aherwar *et al.*, 2020), interconnected type (Zhang *et al.*, 2020c), short fiber (Ding *et al.*, 2002)/whisker (Cao *et al.*, 1990), continuous fiber (Dutta, 2000), singular metal cored (Gupta and Sharon, 2010) and sheet reinforced (Gupta and Sharon, 2010) MMCs. With respect to the microstructure of the composite, factors such as the percentage of reinforcements, its type, shape, size, thermal expansion coefficient, orientation and distribution, etc. plays a significant role in

determining the properties (Dermarkar *et al.*, 2006). The properties can be estimated based on ideal conditions and not considering interaction between matrix and the reinforcement.

The reinforcement material should be uniformly distributed in the matrix to prevent localized plastic deformation and other local variation of properties (Arsenault *et al.*, 1991). Lloyd (1991) synthesized SiC reinforced AA6061 composites and observed localized strain and particle cracking in T6 tempered condition and it is attributed to SiC particle clusters that are subjected to triaxial stress and lead to premature failure of the material. Hence, the reinforcement distribution is very important.

Microstructural Evolution Using Different Reinforcement Materials

Fiber Reinforced MMCs

There are different types of fibers in MMCs like metal (Chang *et al.*, 2019), ceramic (Patil *et al.*, 2020), carbon, fiberglass (Samanta *et al.*, 2018), etc. The properties of the composite are isotropic for random orientation of discontinuous type fibers. For continuous type fibers, the properties are anisotropic for uni-direction alignment. Several other orientations such as multi-direction in-plane alignment exhibits isotropic properties. Apart from orientation, the behavior of MMCs also depends on the aspect ratio of the fibers (Shirvanimoghaddam *et al.*, 2017). Kim (2008) conducted elastic stress analysis to study the effect of fiber aspect ratio in short fiber-reinforced composites. He found significant effect of aspect ratio in composite strengthening mechanisms.

Continuous fiber composites can be classified into unidirectional (Chun and Daniel, 1997) or laminated (Chang *et al.*, 2019) composites, which in general exhibit enhanced strength but limited ductility (McWilliams and Yen, 2016). The fibers in general are strong compared to soft and ductile metallic matrix. The fibers can be randomly oriented also, as synthesized by Mizumoto *et al.* (2005) by dispersing SiC fibers in AZ91 alloy. Fiber arrangement plays a very important role in the mechanical response and Werwer *et al.* (1998) studied this phenomenon using finite elemental analysis. Three deformation mechanisms were stated for hexagonal, square and random arrangements, i.e., deformation with the orientation in a shear band (hexagonal and random), bowing-out mechanism (predominantly in square) and sharp bends (in non-regular arrangements). (Nardone and Prew, 1986) incorporated discontinuous SiC in Al and observed enhancement of yield strength. The difference in the thermal expansion coefficient of SiC and the matrix leads to an increased dislocation density.

Kurumlu *et al.* (2012) reinforced Al MMC with 15 vol% Al_2O_3 fibers synthesized using squeeze-casting method led to the formation of work hardened zones around fibers exhibiting increased dislocation densities during creep.

Samanta *et al.* (2018) used selective laser melting to fabricate glass fiber – reinforced metal matrix composites. The SEM images showed good fusion of glass fibers with Al matrix and these fiber bundles were uniformly covered by the melted powders of Al.

Particulate Composites

The reinforcement composed of particles of any configuration that are randomly distributed or dispersed with a defined orientation in a metallic matrix. Ibrahim *et al.* (1991) reviewed different processes used to synthesize particulate reinforced MMCs. They listed out several factors such as wetting, chemical interaction and reducing oxide formation to enhance interfacial bond strength in MMCs (Ibrahim *et al.*, 1991).

Ganesh *et al.* (Ganesh and Chawla, 2005) observed that the reinforced SiC particles get preferentially oriented along the extrusion axis of AA2080 composite that influences its tensile behavior. Increased volume fraction of SiC reinforced particles reduced the degree of orientation, and it was attributed to the reduced mean free path between SiC particles. This particle orientation anisotropy led to anisotropy in mechanical behavior and that was also validated using microstructure-based FEM modeling.

McNelly *et al.* (1977) devised fine-grained zinc based MMCs with increased volume fraction of W or Al_2O_3 particulate reinforcements and observed yield strengths of unusual values at low homologous temperatures and it is attributed to work hardening due to geometrically necessary dislocations generated by these stiff and incoherent particles.

Wu *et al.* (2019) conducted microstructure-based micromechanical modeling of fracture of SiC reinforced A359 MMC and identified important deformation and failure mechanisms by considering several factors related to particle geometry such as clustering distance and normalized shape factor. The particle clusters exhibited stress concentrations, especially close to the sharp edges and corners where particle fracture takes place.

Kelen *et al.* (2018) synthesized novel AZ91D alloy reinforced with TiNi alloy particles via hot-pressing. The microstructure consisted of α -solid solution, β - $\text{Mg}_{17}\text{Al}_{12}$ and TiNi particles, and although during processing, the constituents did not react with each other but they exhibited good bonding.

Huang *et al.* (2018) studied the microstructure and mechanical properties of tungsten carbide (WC) particle reinforced Al MMCs synthesized using friction stir processing (FSP). SEM images confirms the uniform bonding of WC with Al matrix. WC particles led to dynamic recrystallization and also hindered their growth.

Song *et al.* (Song and Huang, 2008) conducted experiments and simulations to study the effect of SiC particle size on the fracture toughness of Al MMCs. With increase in size and volume fraction of the reinforcement constituent, aging time and temperature, the fracture toughness decreases. This is because precipitation strengthening decreases the fracture toughness.

Wang *et al.* (2014a) synthesized a new particulate reinforced MMC comprising of soft Al matrix, soft alloy core such as Fe and hard intermetallic Al_5Fe_2 shell. Due to the enhanced ductility of the matrix and core, the crack tip gets blunt during crack propagation and overall the composite exhibits enhanced strength and plasticity.

Fig. 1 Microstructures of as-fabricated composite: (a) optical microstructure, (b) scanning electron image, (c) back-scattered electron image and EDS analysis of one reinforcing particle and (d) SEM micrograph of one reinforcing particle. Insert in (b) is the morphology of corresponding eutectic Si phases and insert in (d) is the high magnification image of the particulate shell. From Zhang, J.Y., *et al.*, 2020b. Simultaneously strengthening and toughening a core-shell structured particulate reinforced aluminum alloy-based composite by solid solution treatment. *Journal of Alloys and Compounds*. 842, 155765. doi:10.1016/j.jallcom.2020.155765.

Zhang *et al.* (2020b) synthesized core-shell structured particle reinforced A356 alloy based Al MMC via powder thixoforming. The microstructure consists of Al-Si-Ti spheroidal phases with core-shell morphology, primary particles of α -Al, Mg_2Si , eutectic Si phases (needle like shaped as seen in the inset of Fig. 1(b)) and secondarily solidified structures (SSSs) as seen in Fig. 1. The core is rich in Ti and the shell consists of dual layered structure rich in Si and Al respectively as seen in EDS analysis in Fig. 1(c). Solution treatment reduced SSSs and dissolves eutectic Si. The primary α -Al particles and eutectic α -Al phases get interconnected. The Si rich ternary τ_1 ($\text{Al}_5\text{Si}_7\text{Ti}_{12}$) – phase particles transforms into Al-rich (Al, Si) $_3$ Ti-phase particles during solution treatment.

Nanocomposites

Lee *et al.* (2008) studied the microstructure and mechanical properties of in-situ nanocomposites made of Al-Fe system synthesized using press and sinter followed by friction stir processing (FSP). No Al-Fe reaction took place during sintering but during FSP, due to the short reaction time and severe plastic deformation (SPD) led to the formation of reinforcing particles $\text{Al}_{13}\text{Fe}_4$ in-situ. These particles were of micron sized ($\sim 1 \mu\text{m}$) and that led to the ultrafine grain structure of Al matrix.

Yao *et al.* (2015) synthesized SiC reinforced AA6063 composites using powder metallurgy route followed by hot-extrusion. Dynamic recrystallization of the matrix grains is attributed to the increased grain boundary energy present in the milled powders that provides the dynamic force, followed by the plastic deformation strain generated during hot-extrusion.

Li *et al.* (2020) studied the microstructural evolution of B_4C reinforced Ti MMCs using selective laser melting process (SLM). During this process, B_4C reacted with Ti matrix to form TiB whiskers or TiC particles and the former dominated due to poor solid solubility of B in Ti. 0.5 wt% B_4C addition led to a quasi-continuous structure whereas 1 wt% B_4C led to the formation of a continuous network structure.

Carbon nanotube reinforced MMCs

CNTs have increased values of surface area and if it is not uniformly dispersed, it will lead to clusters and hence inhomogeneous property distribution (Agarwal *et al.*, 2016). Bakshi *et al.* (Agarwal *et al.*, 2016) reviewed CNT reinforced MMCs and discussed the CNT dispersion and interfaces involved in different processing techniques such as ball milling, nanoscale dispersion, molecular-level mixing, spray drying, etc. Interface plays a very important role in engineering these composites as the load transfer to the reinforcement (fibers) from the matrix takes place across the interface (Piggott, 1989).

Fig. 2 TEM observations after tensile testing. (a) shows the position of a FIB sample on a tensile fracture surface. (b) Bright field and (c) corresponding dark field TEM images. (d) is an Inverse Fast Fourier Transform (IFFT) image showing a high density of dislocations generated in the Al matrix next to γ - Al_2O_3 nanoparticles. From Chen, B., *et al.*, 2020a Microstructure, tensile properties and deformation behaviors of aluminum metal matrix composites co-reinforced by ex-situ carbon nanotubes and in-situ alumina nanoparticles. Materials Science and Engineering A 139930. doi:10.1016/j.msea.2020.139930.

Chen *et al.* studied hybrid reinforcement of CNTs added ex-situ and in-situ ultrafine γ - Al_2O_3 nanoparticles formed using ball milling and spark plasma sintering (SPS) in Al MMCs (Chen *et al.*, 2020a). In-situ generated nanoparticles led to Orowan strengthening due to the presence of dislocation loops as seen in Fig. 2. During tensile deformation, formation of nanovoids appear around γ - Al_2O_3 nanoparticles that grow to form microvoids. CNT-induced bridging effect prevents further expansion of these microvoids that enhances the tensile ductility of the sample.

Laminate Composites

These are anisotropic as compared to particulate composites, which are isotropic in general. Several researchers synthesized laminate composites using different processes such as ARB (Wu *et al.*, 2010; Liu *et al.*, 2011; Chang *et al.* 2012; Habila *et al.*, 2019), hot-pressing (Zhu *et al.*, 2011), hot rolling (Zhang *et al.*, 2011a,b; Luo *et al.*, 2013). Different laminate composites such as coatings by laser cladding (Yan *et al.*, 2020), Al/Cu/Al joints using explosive welding (Hoseini Athar and Tolaminejad, 2015) have been synthesized for a variety of applications.

Liu *et al.* (2009) synthesized Mg-Al-Zn/Al laminated composites using equal channel angular extrusion (ECAE). The interface consisted of reaction phases such as Mg_2Al_3 and $\text{Mg}_{17}\text{Al}_{12}$ and with increased annealing temperatures the bonding layers got thickened.

Hu *et al.* (2020) first synthesized High Entropy Alloy (HEA)-intermetallic laminate composites formed between CoCrFeNi HEA and Al sheets prepared using solid diffusion welding. The SEM image as shown in Fig. 3 consists of three well-connected intermediate layers (L1, L2 and L3) formed between these sheets. L1 composed of fine equiaxed grains of Al_3Fe_2 -type, L2 composed of irregular and lath-shaped of $\text{Al}_{13}\text{Fe}_4$ -type. L3 exhibited dual-phase structure of $\text{Al}_{13}\text{Cr}_2$ -type and $\text{Al}_{13}\text{Fe}_4$. These intermetallic layers exhibited an increased hardness values as compared to HEA and Al sheets.

Porous Materials

To create light materials for applications that require increased compressibility or low Young's modulus, porosity is desired. Several studies have been carried out in this area, especially on lightweight materials. Batista *et al.* (2019) synthesized MWCNT reinforced porous Al MMCs using cold pressing followed by sintering for wear resistant hard coatings. Dele-Afolabi *et al.* (2018) developed alumina-Ni composites of porosity close to 57% using rice husk (RH) and sugarcane bagasse (SCB) as pore forming agents. Formation of a $\text{Ni}_3\text{Al}_2\text{SiO}_8$ (spinelloid) phase in RH type and NiAl_2O_4 spinel in SCB type led to fine and dislocated grain

Fig. 3 SEM photograph of the CoCrFeNi/Al HILC. From Hu, Y., *et al.*, 2020. Microstructure characteristics of a high-entropy-alloy intermetallic laminate composite. *Materials Letters* 273, 127937. doi:10.1016/j.matlet.2020.127937.

structures respectively. Porous structures can aid in biocompatibility, as studied by Chasali *et al.* (2019) for Al_2O_3 whiskers and Si_3N_4 particle reinforced Mg MMCs prepared via microwave sintering. Ethylene glycol was used as space holder agent that led to the formation of porous structure.

Microstructural Evolution During Processing

Fabrication techniques can be classified into solid, liquid, gas state and in-situ processes (Bauri *et al.*, 2018). Some of the methods in solid-state processing include powder metallurgy methods (wet and dry method), diffusion bonding, mechanical alloying, spark plasma sintering etc. Casting, liquid infiltration, preform impregnation, spray deposition, pressureless infiltration, ultrasonic infiltration belong to the category of liquid-state processing. Deposition techniques such as chemical vapor deposition, physical vapor deposition are some of the gaseous methods. The microstructural aspects of some of these techniques is discussed.

Casting

Near net shaped fabrication, uniform distribution of reinforcements and control in solidification conditions are some of the advantages of casting route for material synthesis. Particle distribution during casting is influenced by several factors like agglomeration, sedimentation, melt rheology, matrix-particle interactions, etc. (Hashim *et al.*, 2002). Particle-matrix interactions can be long-range and short-range in the form of solute field interactions (Sekhar and Trivedi, 1991) and viscous drag forces respectively (Asthana and Tewari, 1993). It also influences the microstructure by altering the solute concentration gradient near the tip of dendrite and hence affecting the advancing interface (Dutta and Surappa, 1998). Sekhar *et al.* (Sekhar and Trivedi, 1991) observed dendritic tip splitting or dendritic to cellular transition with the presence of reinforcements. Surappa (1997) studied the solidification processing used for synthesizing discontinuously reinforced metal matrix composites (DRMMC). Among different possible microstructures, he classified the solidification front into plane, cellular and dendritic, which is illustrated in Fig. 4. Under different solidification conditions like engulfment (uniform distribution) and entrapment (micro segregation), he discussed the concept of particle distribution map by adapting different process parameters.

A growing crystal during solidification could either reject or engulf the particle (Asthana and Tewari, 1993) and this is based on fluid dynamics, thermodynamics, surface chemistry and other interaction phenomena. In Fig. 4, the dendritic solidification front looks complicated with different possibilities of microstructures w.r.t the interaction with either primary or secondary dendritic arm.

Liquid Infiltration

To incorporate large volume fraction of reinforcement and synthesize materials with complex shapes, a liquid phase (molten metal matrix) fills the gap between the reinforcement material such as ceramic particles, fibers, etc., via capillary force or an external pressure (Sree Manu *et al.*, 2016). There are several categories of infiltration process such as pressure die, gas pressure, ultrasonic, centrifugal, lorentz force and squeeze casting.

Shin *et al.* (2019) studied the evolution of microstructure of monomodal and bimodal sized SiC reinforced T6 treated Al7075 composites synthesized using liquid-pressing process. Hard spherical Mg_2Si precipitates were dispersed homogeneously in the matrix that reduced to smaller sizes during the precipitation hardening.

Lee *et al.* (2020) synthesized TiC- (JIS SKD11) steel composite using this process and studied the microstructure and mechanical properties. The SEM micrographs of TiC powder, preform and the composites are presented in Fig. 5. Irregular shaped TiC (Fig. 5(a)) were then pressed to create a preform and sintered (Fig. 5(b)). These preforms are placed along with steel ingots in the crucible and heated by vacuum induction melting. Later they are pressurized using argon gas, followed by pouring into the mold. A homogeneous distribution of the reinforcement can be observed in Fig. 5(c). Due to the dissolution and re-precipitation

Fig. 4 Schematic showing various possible microstructures in a composite casting. Adapted from Surappa, M.K., 1997. Microstructure evolution during solidification of DRMMCs (discontinuously reinforced metal matrix composites): State of art. *Journal of Materials Processing Technology*. 63, 325–333. doi:10.1016/S0924-0136(96)02643-X.

Fig. 5 Microstructure of (a) raw TiC powders, (b) sintered TiC preform, and (c, d) TiC-SKD11 composites fabricated by the LPI process. From Lee, Y.H., *et al.*, 2020. Microstructure and mechanical properties of lightweight TiC-steel composite prepared by liquid pressing infiltration process. *Materials Characterization*. 162, 110202. doi:10.1016/j.matchar.2020.110202.

of the reinforcement, a core-rim microstructure can be seen in **Fig. 6**. Nanoindentation tests carried out at the core-rim interfaces exhibited similar trends compared to the tests on the hard TiC cores.

Preform Impregnation Process

This process involves replication of structure of a material with the metal (mortar), adsorption of brick material into the mortar followed by hot-compaction. Xiong *et al.* (2015) synthesized bioinspired graphene and copper artificial nacre metal matrix

Fig. 6 (a) Schematics and detailed microstructure of impression after nano-indentation on (b) TiC core; (c) TiC core-rim interface; (d) TiC rim; (e) TiC/SKD11matrix interface; and (f) matrix alloy. From Lee, Y.H., *et al.*, 2020. Microstructure and mechanical properties of lightweight TiC-steel composite prepared by liquid pressing infiltration process. *Materials Characterization*. 162, 110202. doi:10.1016/j.matchar.2020.110202.

composite. Copper was first replicated to that of an ordered porous structure made of fir wood, followed by reduced graphene oxide (RGrO) absorption into this porous preform and then compaction using hot-pressing method. As seen in Fig. 7, the composite exhibited brick (RGrO) and mortar (copper) type microstructure. RGrO was dispersed homogeneously and aligned in Cu matrix due to smaller wall thickness of ordered pores.

Spray Deposition

This process involves depositing atomized stream of particulate containing molten metal onto the substrate (White and Willis, 1989). The process parameters that can influence the microstructural evolution are atomization temperature, melt stream diameter, spray height, substrate's rotational velocity, atomization gas pressure and powder transportation pressure (Chen *et al.*, 2009). This method of synthesis ensures less relative contact time between the molten metal and the reinforcement and therefore they exhibit enhanced metal-ceramic interface integrity (White and Willis, 1989).

Chen *et al.* (2009) studied the microstructural evolution of SiCp/Al-8.5Fe-1.3V-1.7Si developed using spray co-deposition technology. The microstructures of both as-deposited and extruded materials exhibited lamellar morphology, which was attributed to the substrate's rotation during deposition. It was also denoted as tree ring structure (TRS) and it consisted of bands of low and high particle concentrations.

Selective Laser Melting (SLM)

This technique uses a powered laser to melt the powders and fuse them together (Ivanov *et al.*, 2017; Zhao *et al.*, 2018). Several parameters such as laser power, scan speed etc. could be tailored to achieve different microstructures (Khorasani *et al.*, 2019). Rong *et al.* (2016) synthesized WC reinforced Inconel 718 composites using SLM with a novel graded interface with a diffusion layer

Fig. 7 (a) Layered porous structure of fir wood (the wood was carbonized for SEM observation). (b) Monolithic fir-templated porous Cu preform with a typical size of $2 \times 1.5 \times 1.5 \text{ cm}^3$. High and low magnification SEM images indicate a good replication of the microstructure of fir wood. From Xiong, D.B., *et al.*, 2015. Graphene-and-copper artificial nacre fabricated by a preform impregnation process: Bioinspired strategy for strengthening-toughening of metal matrix composite. ACS Nano 9, 6934–6943. doi:10.1021/acs.nano.5b01067.

formed due to in-situ reaction between the constituents. This changed the wear mechanism to adhesive from severe abrasive and enhanced the wear performance of the composite.

Chen *et al.* (2020c) synthesized in-situ TiC/Inconel 625 nanocomposites using selective laser melting process and studied the effect of laser fluence on the microstructure. “Fish-scale” morphology in IN625 was observed and the columnar dendrites get refined with increased laser fluence values. Increased dislocation density was observed due to the difference in CTE between the matrix and the reinforcement.

In-Situ Processes

To eliminate the brittle layer at the matrix-reinforcement interface and create fine particulate reinforcements with uniform distribution, composites synthesized using in-situ processes exhibit enhanced mechanical properties (Yang *et al.*, 2003; Wang *et al.*, 2004; Tian *et al.* 2014).

Ma *et al.* synthesized TiB_2 reinforced Al-Zn-Mg-Cu composite using an in-situ mixed salt method consisting of dipotassium titanium hexafluoride and potassium fluoroborate (Ma *et al.*, 2020). The TEM image of the composite shows uniform distribution of TiB_2 nanoparticles in the matrix as seen in Fig. 8(a). The interface precipitation was governed by the faceted TiB_2 nanoparticles (Fig. 8(b)) that led to effective interface strengthening by minimizing the mismatch of the interface and maximizing the coherency.

Powder-Metallurgy Processing

Problems with wetting and interfacial bonding in conventional methods of synthesis could be overcome in powder-metallurgy processing (Manohar *et al.*, 2018). Zhang *et al.* (2020a) used SiC-graphite and SiC-graphene as reinforcements into A355 Al-Si alloy matrix using powder metallurgy route comprising ball milling, compaction and hot-pressing. Microstructural evolution of bulk composites comprised of carbonaceous defects formed during ball milling, well dispersed SiC-graphene nanosheets and the formation of Al_4C_3 needles during hot pressing. Fig. 9 shows TEM micrograph of Al-Gt (A355 + SiC + graphite) and Al-Gn (A355 + SiC + graphene nanosheets). A nanostructured composite with an uniform distribution of reinforcement is obtained.

Fig. 8 (a) Bright-field TEM image showing homogenous distribution of TiB₂ nanoparticles in the Al-Zn-Mg-Cu matrix grain, (b) STEM-HAADF image showing a typical TiB₂/Al interface at the as-quenched state and (c) schematic drawing illustrating the faceted shape of the TiB₂ nanoparticle. Secondary Deformation Processing

Bulk-forming and sheet-forming constitute secondary deformation processes, where the tool and surfaces of the deforming material are always in contact. MMCs can be synthesized using several processes, like extrusion, forging and rolling etc.

Extrusion

Extrusion can lead to discontinuous fibers to align in the axial (extruded) direction preferentially and this process can break down the reinforcements, reduce porosity and enhance bonding. Uan *et al.* (2001) synthesized in-situ Al-Al₃Ni composite using

Fig. 10 EU200, transverse section of position 1 which shows numerous tangled dislocations and many of them pinned by adjacent Al_3Ni particles. The subgrains are marked by two arrows. From Uan, J.Y., Chen, L.H., Lui, T.S., 2001. On the extrusion microstructural evolution of Al- Al_3Ni in situ composite. *Acta Materialia*. 49, 313–320. doi:10.1016/S1359-6454(00)00309-8.

directional solidification and studied the microstructural evolution post extrusion at 200°C and 400°C. Microstructures at 200°C composed of tangled dislocations pinned by Al_3Ni fibers in the presence of small subgrains as seen in Fig. 10 whereas at higher temperatures they evolve upto 3–4 μm that have low density of dislocations. The polygonization process is depicted in Fig. 11.

Forging

Forging is a deformation process involved with localized compressive forces, which can be carried out with or without the application of heat (Ozerov *et al.*, 2019).

Deng *et al.* (2010) studied hot forged SiCp/AZ91 composites synthesized using stir casting route. Fig. 12 shows the optical microstructures of as-cast and as-forged composites at different temperatures. Hot forging enhanced the particle distribution and it led to basal texture formation that weakened with increased forging temperatures. Deformed structures decrease and finer equiaxed grain structure increase with temperature. These uniformly distributed SiC particles activated dynamic recrystallization and this phenomenon improved with temperature.

High pressure torsion (HPT)

The materials in this technique are subjected to compressive forces similar to that of forging, but they are also subjected to torsional straining (Zhilyaev and Langdon, 2008). Aristizabal *et al.* (2020) subjected CNT reinforced Ni matrix composites under high pressure torsion (HPT) and studied their microstructural evolution. Formation of nickel carbide was observed in these composites with enhanced thermal stability and CNTs restricted the grain growth at higher temperatures.

Kawasaki *et al.* (2016) stacked disks of Al-1050 and ZK60A and processed using HPT. This process introduces a lot of vacancy-type defects and this leads to lower activation energy for diffusion bonding of Al and Mg phases.

Equal channel angular pressing (ECAP)

This technique involves severe plastic deformation but without changing the geometry of the specimen (Semenova *et al.*, 2018). Abbas *et al.* (Abbas and Huang, 2020) studied the microstructure of AZ91 MMCs reinforced with WS_2 prepared using stir casting method followed by ECAP. The microstructures consisted of α -Mg, Al_5Mn_3 , WS_2 , β - $\text{Mg}_{17}\text{Al}_{12}$ and Mg_2Al_3 . The precipitation was discontinuous and it is attributed to the cellular breakdown of secondary precipitates. Increased ECAP passes induced cracks in the precipitates.

Diffusion Bonding

Diffusion bonding comprises of plastic deformation of asperities, followed by change in void morphology close to the bonding interface and finally their contraction and the removal (Derby and Wallach, 1984). Vacuum hot pressing (VHP), step pressing, hot-die molding, superplastic forming, hot isostatic pressing are few examples of the synthesis methodologies (Everett and Arsenault, 1991).

He *et al.* (2003) used diffusion bonding method to produce a TiAl/steel composite with barrier layers using foils of V, Cu and Ti. The synthesis was carried out using a vacuum induction heating machine. At the interface of TiAl/Ti, a dual phase $\text{Ti}_3\text{Al} + \text{TiAl}$ and solid solution of Ti was formed that contributed to increased strength.

Guo *et al.* (Guo and Derby, 1993) used diffusion bonding consolidation method to fabricate Ti-6Al-4V/SiC fiber composite. At 870°C, it exhibited complete matrix-matrix bonding with fine and equiaxed ($\alpha + \beta$) structure. Below 770°C, due to poor inter-diffusion it does not provide good composite bonding. Above 1070°C, SiC crystals and grains grow that reduce the properties of the composite.

Fig. 11 Schematic diagrams showing the microstructural evolution during 200°C extrusion [(a) and (b): longitudinal sections; (c): transverse section]. From Uan, J.Y., Chen, L.H., Lui, T.S., 2001. On the extrusion microstructural evolution of Al-Al₃Ni in situ composite. *Acta Materialia*. 49, 313–320. doi:10.1016/S1359-6454(00)00309-8.

Accumulative Roll Bonding (ARB)

A severe plastic deformation technique involving rolling, ARB involves processes such as degreasing and wire-brushing, stacking, roll-bonding, cutting and these steps are repeated (accumulated) (Tsuji, 2011). Danielle *et al.* (Magalhães *et al.*, 2020) synthesized AA1050/AA7050 multilayered composites using Asymmetric Accumulative Roll-Bonding (AARB) technique. Initial rolling of AA1050 in room temperature was followed by annealing whereas the overaged AA7050 was rolled at higher temperatures (400°C). The former alloy exhibited equiaxed grain structure whereas the latter had elongated grain structure. Fig. 13 shows different microstructures generated after AARB treatment with different preheating conditions and different number of cycles. The interface zone shows no debonding and due to asymmetric conditions, layers exhibit wavy-patterns.

Chen *et al.* (2015) investigated the deformation inhomogeneities of AZ31 – AA1100 laminated composites that arise due to the different deformation behavior of metals. Initial ARB cycles saw local necking in Mg layers, which saw more fractures. Hence, layers of AZ31 gets bent and discontinuous whereas Al layers fill the neighboring region. Final microstructure consists of a continuous soft Al matrix with hard Mg laminated fragments.

Fig. 12 Optical micrograph of SiCp/AZ91 composite of (a) as-cast and as-forged at the temperatures of (b) 320°C, (c) 370°C, (d) 420°C, (e) 470°C and (f) 520°C. From Deng, K.K., *et al.*, 2010. Microstructure evolution and mechanical properties of a particulate reinforced magnesium matrix composites forged at elevated temperatures. *Materials Science and Engineering A* 527, 1630–1635. doi:10.1016/j.msea.2009.10.053.

Explosive Shock Consolidation

By using shock waves, this process results in interparticle bonding due to powders subjected to severe deformation (Meyers and Wang, 1988). Raghukandan *et al.* (2004) prepared Al- 30 vol%SiC_p composites using underwater shock consolidation method by adapting detonation velocity of 6.9 km/s. Microstructures did not consist of reaction products like brittle Al₄C₃ that is sensitive to corrosion and mostly detrimental. The high shock energy led to high consolidation pressure of about 7 GPa which densified the composite.

Vorozhtsov *et al.* (2017) used nanodiamonds and aluminum nanoparticles and synthesized composites with high density and enhanced mechanical properties. A schematic of explosive consolidation process is shown in Fig. 14 where deformation flows remove the oxide layer and the nanodiamond particles exert compressive force on the aluminum particles, which leads to the formation of metastable aluminum phase.

Plating and Deposition Techniques

Electrodeposition

A bottom-up approach involved in depositing ions reduced at the cathode, electrodeposition technique can be used to prepare MMCs with high purity. Rekha *et al.* (Rekha and Srivastava, 2019) studied microstructural evolution of ZnNi-GO composite coatings synthesized using electrodeposition technique. Several intermetallic phases like γ -NiZn₃, δ -Ni₃Zn₂₂, and γ -Ni₅Zn₂₁ were identified in ZnNi-GO coatings along with pure Zn phase nucleated and grew over GO.

Fig. 13 Microstructural evolution of the multilayered composite sheets of AA1050/AA7050 Al alloy processed after a different number of cycles at: (a, c, e) 450 °C; and (b, d, f) 500 °C. ND = normal direction and RD = rolling direction. From Magalhães, D.C.C., Sordi, V.L., Kliauga, A.M., 2020. Microstructure evolution of multilayered composite sheets of AA1050/AA7050 Al alloys produced by asymmetric accumulative roll-bonding. *Materials Characterization* 162, 110226. doi:10.1016/j.matchar.2020.110226.

Wang *et al.* (2020) developed layered CNT/Cu composites with heterostructures using electrodeposition, followed by spark plasma sintering. Optimizing CNT content in the layered films was carried out by tailoring the deposition current density. The mechanical properties exhibited a balance between the strength and ductility due to this microstructure.

Wang *et al.* (2019) developed activated carbon (AC) reinforced Ni MMCs using facile electrodeposition technique for electrode applications. Ni films without AC exhibited elongated and flaky structure and with AC showed a cactus like 3D flower like morphology that enhanced the surface area, which is beneficial for hydrogen evolution reactions.

Chemical vapor deposition (CVD)

CVD method is a vacuum deposition technique that can homogeneously deposit materials using precursors that vaporize and react with each other to form composites. One of the first fabrications of carbon fiber reinforced Al MMCs were carried out by Baker *et al.* (1972) and Jackson *et al.* (1972). They used CVD from tri-isobutyl aluminum to develop Al coated C fibers.

He *et al.* (2009) synthesized CNT reinforced Al MMCs using CVD technique, as shown in the microstructure in Fig. 15. The morphology of in-situ synthesized CNT-Al powders is spherical as seen in the SEM image in Fig. 15(a). Apart from the uniform dispersion of CNTs due to this technique, the formation of Al_4C_3 as a thin layer at the interface provides good interfacial bonding.

Ultrasonic Treatment

The technique of ultrasonication has been used for refinement of the microstructure (Yang *et al.*, 2018), dispersion of reinforcement via transient cavitation and acoustic streaming (Yang *et al.*, 2004), removal of hydrogen (Liu *et al.*, 2017), etc.

Hu *et al.* (2018) used ultrasonic treatment prior to squeeze casting to synthesize nano-SiCp reinforced A356 composites. A356 consist of acicular long heterogeneously distributed eutectic Si and coarse dendrites of primary $\alpha(\text{Al})$. Addition of SiCp reduced the

Fig. 14 Schematic of the consolidation process of nanopowders under explosive compaction. From Vorozhtsov, S., *et al.*, 2017. Structural and mechanical properties of aluminum-based composites processed by explosive compaction. *Powder Technology* 313, 251–259. doi:10.1016/j.powtec.2017.03.027.

Fig. 15 (a) SEM image of a CNT–Al composite powder, (b) HRTEM image of a typical CNT, showing a well-graphitized multiwalled nanotube. From He, C.N., *et al.*, 2009. Mechanical properties and microstructures of carbon nanotube-reinforced Al matrix composite fabricated by in situ chemical vapor deposition. *Journal of Alloys and Compounds*. 487, 258–262. doi:10.1016/j.jallcom.2009.07.099.

dendrite length and refines eutectic Si. These dendrites change their morphology to rosette crystals and equiaxed grains. Uniform distribution of nano-SiCp takes place due to ultrasonic treatment, as shown in the schematic in Fig. 16(a). Nucleation of primary $\alpha(\text{Al})$ takes place when the melt is close to the liquidus temperature and dendritic growth is restricted by the nano-SiC particles.

Different Types Microstructures Involved

In this section, the microstructures of composites with Al, Mg and Ti matrix configurations are discussed. Al and Mg based composites are lightweight and are used in aerospace and automotive applications whereas Ti based composites are commonly used for high-temperature applications.

Fig. 16 Schematic diagram of microstructure evolution of nano-SiCp/A356 composite melt before eutectic reaction: (a) Uniformly distributed nano-SiCp in composites melt; (b) Nucleation of primary $\alpha(\text{Al})$; (c) Growth of $\alpha(\text{Al})$ grains. From Hu, K., *et al.*, 2018. Effects of nano-SiCp content on microstructure and mechanical properties of SiCp/A356 composites assisted with ultrasonic treatment. Transactions of Nonferrous Metals Society of China. 28, 2173–2180. doi:10.1016/S1003-6326(18)64862-9.

Aluminum Metal Matrix Composites

Aluminum is lightweight, has good thermal conductivity and has excellent corrosion resistance. Chidambaram *et al.* described the metallographic preparation of aluminum-alumina MMCs (Chidambaram and Bhole, 1997). Since these reinforcement materials are hard particles, conventional alloy polishing practices cannot be perceived. Among several methods, Buehler method that involved grinding on SiC paper followed by diamond polishing on cloth and etching with 5% HF (49%) in distilled water was optimum for revealing the microstructure.

Kundu *et al.* (2013) studied the microstructure of SiC reinforced Al MMCs prepared using manual stir casting. Microstructural analysis showed uneven distribution of SiC which was attributed to the difference in its density between molten metal.

Xiao *et al.* (2019) studied the microstructural evolution of a hypereutectic Al-20Si alloy containing x wt% TiB_2 particles. The microstructure consisted of eutectic structures with primary Si phase and TiB_2 particles not only acted as substrate for heterogeneous nucleation of primary Si, but also hindered element diffusion and restricted its growth.

Chelliah *et al.* (2017) used liquid stir-casting method and injected cross-linked polymer powder into Mg, AZ91 and AE44 alloys to synthesize in-situ SiCNO phases in Mg MMCs. The microstructural evolution of PP900-AE composite specimen is shown in Fig. 17. Coarse sized Mg_2Si crystals are dispersed along with acicular Al_xRE_y as shown in Fig. 17(a).

Magnesium Metal Matrix Composites

Magnesium based alloys and composites are widely used in automobile, biomedical, electromagnetic shielding and other specialty applications. Horvitz *et al.* (Horvitz and Gotman, 2002) used self-propagating high-temperature synthesis (SHS) to develop in-situ MgAl_2O_4 – TiAl composites with fine interpenetrating networks of ceramics and intermetallics. TiAl (γ) + Ti_3Al (α) lamellar structure led to the enhancement of the mechanical properties.

Reinforced with Al_2O_3

Zhong *et al.* (2014) synthesized 1.5 vol% nano Al_2O_3 reinforced AZ31 using disintegrated melt deposition (DMD) followed by hot-extrusion. Extruded microstructures revealed fine grains and particles of nano-alumina aligned with the extruded direction that act as nucleation sites for enhanced recrystallization.

de Castro *et al.* (Castro *et al.*, 2019) synthesized 10 vol% Al_2O_3 reinforced Mg machining chips using high pressure torsion (HPT). Chips of hard phase Mg slide along Al_2O_3 particles and the composite consists of smaller crystallite size that improved hardness and exhibits greater resistance against creep at room temperature.

Srivastava *et al.* (Srivastava and Chaudhari, 2018) studied the evolution of microstructure of Al6061- nano Al_2O_3 synthesized using ultrasound solidification technique. Al_2O_3 dispersed uniformly in the melt due to intense ultrasonic vibrations. Pure Al_2O_3 alloy fractured due to its dendritic structure and the presence of micro-porosities but the composites exhibited mixed mode fracture with no presence of any particle debonding characteristics.

Reinforced with MgO

Goh *et al.* (2007) studied the addition of nanosized MgO reinforced Mg composites using disintegrated melt deposition (DMD) technique. TEM studies on these composites revealed enhanced interfacial integrity between the matrix and the reinforcement.

Fig. 17 Microstructural evolution of AE44 matrix composites fabricated by in-situ processing (a) dispersion of coarsened Mg_2Si crystals and Al_xRE_y intermetallics (b) dendritic morphology of Mg_2Si crystal (c) dispersion of fine-sized Al_xRE_y intermetallics and (d) dispersion of fine-sized SiCNO particles. From Chelliah, N.M., Singh, H., Surappa, M.K., 2017. Microstructural evolution and strengthening behavior in in-situ magnesium matrix composites fabricated by solidification processing. *Materials Chemistry and Physics*. 194, 65–76. doi:10.1016/j.matchemphys.2017.03.025.

Cai *et al.* (2018) synthesized Mg-MgO nanocomposites using reactive cryomilling and high pressure consolidation method. These nanocomposites were thermally stable due to strong Zener pinning effect of the in-situ formed MgO nanoparticles located at the grain boundaries with the matrix.

Reinforced with SiC

Saravanan *et al.* (Saravanan and Surappa, 2000) synthesized Mg-30 vol% SiC using melt stir process. SiC particles led to the formation of cellular-dendritic interface in the composite as compared to a typical dendritic structure for pure Mg.

Reinforced with Y_2O_3

Han *et al.* (Han and Dunand, 2000) studied yttria reinforced dispersion strengthened magnesium. Zener pinning of yttria led to reduction in grain sizes of extruded materials to 0.88 μm . Hassan *et al.* (Hassan, 2011) synthesized nano-yttria reinforced magnesium nanocomposites using both blend-press-sinter powder metallurgy process and disintegrated melt deposition (DMD) technique followed by extrusion at increased temperatures. With increase in Y_2O_3 particulates, the volume fraction of recrystallized grains also increased. The nano- Y_2O_3 particulates undergoes pinning the recrystallized magnesium grains leading to its restricted growth.

Reinforced with ZrO_2

Hassan *et al.* (2007) developed nano-zirconia reinforced magnesium nanocomposites using blend-press-sinter powder metallurgy process. Results showed significant grain refinement with minimal porosity post hot-extrusion.

Reinforced with CNTs

Xiang *et al.* (2019) constructed CNTs/Mg laminated composite structure by using electrophoretic deposition technique combined with hot press sintering and hot rolling to generate a micro-nano layered structure. The CNT layers cause high back stress that prevent dislocation slip and hinder the crack propagation.

Titanium Metal Matrix Composites (TMMC)

TMMCs are good candidates for aerospace applications (Liu *et al.*, 2006), for its enhanced oxidation resistance, excellent strength-to-weight ratio and high temperature applicability. Different reinforcements include discontinuous type such as TiB whiskers (Ravi Chandran *et al.*, 2004; Morsi and Patel, 2007), TiC (Geng *et al.*, 2008), TiN (Suárez-Martínez *et al.*, 2020), B_4C (Nartu *et al.*, 2020), graphene (Cao and Liang, 2020), TiB_2 (Liu *et al.*, 2020a), SiC (Liu *et al.*, 2020b), etc. synthesized either using powder metallurgy (in-situ or ex-situ) route or rapid solidification method as ingot metallurgy is not permissible for highly reactive titanium (Hayat *et al.*, 2019).

Several methods such as physical vapor deposition (Lobley and Guo, 1999), tape casting (Lobley and Quo, 1998), induction plasma deposition (Pank and Jackson, 1993) can be used for continuous (fiber) type reinforcements.

Bejjani *et al.* (2016) studied the adiabatic shear bands (ASB) produced in segmented chips of Ti-MMCs when they are subjected to machining. During the formation of chip, dynamic recovery takes place and the large grains containing high-energy configurational dislocations leads to its rearrangement within elongated cells. With increase in misorientations, subgrain boundaries evolve and leads to evolution of nanograin structure.

Ozerov *et al.* (2019) studied the microstructural evolution during multiaxial forging (MAF) of Ti/TiB MMC produced due to spark plasma sintering (SPS) process. Ti and TiB₂ reacted to form TiB whiskers. Dynamic recrystallization occurred during forging at 700–850°C leads to dislocation free recrystallized areas and shortened TiB whiskers.

Kim *et al.* (Kim and Choi, 2004) studied the microstructural influences and process conditions on consolidation behavior of SiC fiber/Ti-6Al-4V foil MMCs. At a consolidation pressure of 30 MPa at 900°C, it exhibited a heterogeneous microstructure consisting equiaxed α , widmanstätten α and transformed β . Different geometrical arrangements of foil-fiber-foil type can lead to different levels of densification and hence the mechanical properties.

Vancheeswaran *et al.* (1997) developed a consolidation path planning simulations to arrive at pre-determined microstructure of a fiber reinforced composite. A micromechanical model consisting of local linear approximations was chosen to achieve enhanced mechanical performance for Ti-6Al-4V/SCS-6 composite.

Li *et al.* (2017) used selective laser melting technique to study the phase transformation and texture evolution of TiAl/TiB₂ in-situ MMCs that exhibited enhanced nanohardness. The microstructure consisted of α_2 (Ti₃Al), γ (TiAl), B₂, TiB₂ and TiB phases. With increase in TiB₂ content, refined grain structure was observed. It also led to texture strengthening of basal ($\{0001\} <11\bar{2}0>$), prismatic ($\{10\bar{1}0\} <11\bar{2}0>$) and pyramidal fibers ($\{10\bar{1}1\} <11\bar{2}0>$ and $\{11\bar{2}2\} <11\bar{2}3>$) of Ti₃Al phase.

Guo *et al.* (2012) studied reaction between Ti and LaB₆ to synthesize TiB whiskers and La₂O₃ reinforced Ti MMCs synthesized using vacuum arc remelting process, followed by hot rolling. Increased deformation degree led to rotation of whiskers that contributed in enhancement of room-temperature tensile properties.

Hybrid Metal Matrix Composites

Hybrid reinforcements onto MMCs develop synergistic effects and exhibit significant improvement in the properties compared to their counterparts. Zhou *et al.* reviewed progress in hybrid MMCs (Zhou *et al.*, 2020). They discussed common reinforcements used in MMCs. Among continuous reinforcement type, fibers of C, SiC, Al₂O₃, B and wires of steel and W can be used (Zhou *et al.*, 2020). Among discontinuous type, ceramic particles like SiC, Al₂O₃, B₄C, TiB₂, AlN etc., metallic particles like Ti, Cu, Ni, Zr etc., are used. Zhou *et al.* also synthesized micron SiC and CNT reinforced AZ61 alloy composites using powder metallurgy followed by hot-extrusion (Zhou *et al.*, 2019). The novel multi-dispersion process for homogeneous dispersion consisted of CNT adsorption onto SiC surface via hydrogen bonding followed by ball milling.

Li *et al.* (2015) studied the synergistic strengthening effect by preparing Al MMC made of reduced graphene oxide (RGO) and carbon nanotube (CNT), whose planar network led to increased load transfer among the constituents.

Wei *et al.* (2018) fabricated network Ti-6Al-4V/(TiB + TiC) hybrid composites prepared using reaction hot pressing technique exhibits enhanced cyclic oxidation resistance. The reinforcement phases exhibit a 3D network microstructure within bulk composite as seen in Fig. 18, where TiC particles and TiB whiskers are selectively distributed on the Ti-6Al-4V intergranular boundaries. The reinforcement led to the change in the internal microstructure from Widmanstätten lamellae to α -Ti equi-axed grains.

Texture

It is not only the changes in microstructure that influences the material properties, but it is also highly dependent on texture. The processing route decides the texture of the composite, which can influence several properties (Suresh *et al.*, 2013). Texture formation takes place via phase transformation, recrystallization, plastic deformation, etc. (Kestens and Pircgazi, 2016). Secondary processes such as extrusion causes directional alignment of the grains, phases and breaks down the reinforcements and aligns them parallel to streamlines. Sometimes the amount of reinforcement material can enhance the texture, as seen by Li *et al.* (2017) where texture strength of TiAl/TiB₂ in-situ MMCs increased with the amount of TiB₂. Shahani *et al.* (Shahani and Clyne, 1991) studied Al₂O₃ dispersed in Al and found strong texture in the matrix for spherical particle reinforcement and observed weakened texture with increase in aspect ratio. Nucleation enhanced with increasing volume fraction of the particles and among them, large particles stimulate nucleation and fine oxide particles inhibited.

Cold-Rolling Texture

Dan *et al.* (2018) using neutron diffraction and EBSD analysis studied the cold rolling texture evolution of TiB₂ reinforced Al composites. The reinforcement influenced the texture in two different ways, the non-shearable and small TiB₂ particles contributed to dominant $\{112\} <111>$ copper orientation at high strains whereas the clusters of TiB₂ along the grain boundaries and the

Fig. 18 (a) XRD patterns of typical Ti-6Al-4V/(TiC + TiB) composites and as-sintered Ti-6Al-4V, (b) Ideal network microstructure designed for Ti-6Al-4V/(TiC + TiB) composites, (c,d) SEM micrographs. From Wei, S.L., *et al.*, 2018. Interactive effects of cyclic oxidation and structural evolution for Ti-6Al-4V/(TiC + TiB) alloy composites at elevated temperatures. *Journal of Alloys and Compounds*. 752, 164–178. doi:[10.1016/j.jallcom.2018.04.118](https://doi.org/10.1016/j.jallcom.2018.04.118).

recrystallized nuclei led to weak texture. The regions around these clusters was called particle deformed zone and some cube {001} <100> orientations were observed.

Recrystallization Texture

Poudens *et al.* (Poudens and Bacroix, 1996) studied the recrystallization textures in Al-SiC MMCs after subjected to a deformation process. Particle stimulated nucleation (PSN) process creates distorted zones of heterogeneous deformation that yields weak textures, barring small sized shearable particles that result in a strong texture and it is attributed to the shear bands caused during deformation (Lücke and Engler, 1990).

Aging Kinetics of Particle Reinforced Aluminum Metal Matrix Composites

The composite matrix exhibits enhanced dislocation densities due to the presence of reinforcements. Suresh *et al.* (1989) observed accelerated aging in Al-Cu-SiC particulated composites and this phenomenon did not enhance with increase in reinforcement addition. SiC enhances the precipitation kinetics of the composite material in comparison with the material without reinforcement. The dislocation densities are found to be greater at the particle/matrix interface, where the hardening phenomenon was observed to faster by Dutta *et al.* (Dutta and Surappa, 1997) during their studies on the age-hardening characteristics of Al-Cu-SiCp composites and it slows with increasing distance. After the samples are subjected to solutionizing temperature, thermal residual stresses evolve when they are cooled to room temperature before aging. Precipitate nucleation and growth is a function of matrix dislocation density distributions (Dutta and Bourell, 1990) and several models have been proposed in this regard.

Microstructural aspects of age-hardening precipitation reactions in SiC whiskers and particles reinforced Al MMCs using Differential Scanning Calorimeter (DSC) was carried out by Papazian (1988). This method is rapid and precipitation reactions can be detected corresponding to change in enthalpies. The cold rolling effect on aging kinetics of alumina reinforced AA6061 composites was studied by Lee *et al.* (1991) using DSC. Similar to reinforcement addition, it was found that cold rolling produced an increased dislocation density that caused accelerated aging. Christman *et al.* (Christman and Suresh, 1988) studied changes in electrical conductivity behavior to interpret the microstructural aspects of SiC whisker reinforced Al MMCs. As the reinforcement material here is an excellent electron scatterer, the composite exhibited lower conductivity compared to the base alloy (AA2124). During the aging process, the normalized conductivity values of the base alloy and the composite did not vary to a greater extent, except in the beginning where the rate of conductivity declining was greater for the composite than the base alloy.

Corrosion

Imeson *et al.* (Imeson and Bartlett, 1995) linked corrosion phenomenon to the microstructure of SiC reinforced AA2124 MMC directly using TEM. Samples were subjected to a “flash corrosion” etching treatment prior to TEM examination. It was found that the SiC particles and intermetallic precipitates did not have a major role in pit initiation, but the microstructural features comprising of Mg segregation close to SiC interfaces and Mg₂Si was the primary cause.

Study of Interfaces and Interlayers

Thermal Mismatch

Vogelsang *et al.* (1986) used a High Voltage Electron Microscope (HVEM) to study the dislocation generation at the Al/(discontinuous or platlet type SiC) interfaces during cooling after annealing treatment. This was attributed to the high difference in thermal expansion coefficients of Al and SiC that strengthens the composite due to high density of dislocations. Chawla *et al.* (Chawla and Metzger, 1972) investigated the microstructure of W-fiber reinforced Cu composites using dislocation etch pitting technique. They accounted for transverse and axial strains due to the differential shrinkage and also studied the interface shear.

Qu *et al.* (2011) reviewed the thermo-physical properties of MMCs like SiC/metal, C/metal, diamond/metal for thermal management applications. In the case of SiC/Al and C/Al composites, the formation of Al₄C₃ due to interfacial reaction (Etter *et al.*, 2007; Ren *et al.*, 2008) can degrade thermal properties. For SiC/Cu composites, the formation of Cu₃Si influences the reactive wetting (Rado *et al.*, 2000) and hence the thermal properties. Addition of Ti can enhance wettability between SiC and Cu (Krauß *et al.*, 2002). Several studies on the thermal conductivity of diamond reinforced MMCs (Shao *et al.*, 2004; Beffort *et al.*, 2006; Weber and Tavangar, 2007; Molina *et al.*, 2008; Mizuuchi *et al.*, 2010; Dong *et al.*, 2011) shows the importance of interface structure for improved bonding.

Conclusion

Structural factors like periodicity of phase components, phase dimensions, their geometric arrangement, volume fraction and processing conditions are important factors in deciding the final properties of the composites. Interaction between the matrix and reinforcement, and the interface engineering needs to be further understood for a wide range of materials. Metal matrix composites can be synthesized using different processes and hence different microstructures can be achieved. Tailoring these microstructures helps a materials scientist to enhance the performance of the composite developed for a specific application, which the conventional material is not capable of delivering it. Composite materials is a rapidly developing field and with rising socio-economic standards in many countries, this will have a lucrative growth estimated in the coming future.

Introduction

Light weighting has become a necessity for applications in automotive and aerospace sectors and to push prospective buyers for a client decision. With skyrocketing oil costs and policies to embolden cut in greenhouse gas emissions is heavily influencing researchers, scientists, manufacturers and industries to stress on lightweight materials (Gupta and Ling, 2011). Also, adapting lightweight materials to build components such as engines, seats and frames for automobile and airplane would help to reduce CO₂ emissions hence increasing fuel efficiency and control pollution. Magnesium (Mg) has a density of 1.74 g/cc, which is 33% lighter than aluminum, 61% lighter than titanium and 77% lighter than stainless steel, thus making it extremely lightweight structural metal easily available on earth's crust (Kumar *et al.*, 2018b). Additionally, with properties such as high specific strength, excellent castability, resistance to electromagnetic radiation, machinability, mechanical and thermal properties make it attractive to be used for engineering applications (Kaiser and Kainer, 2003). However, plastic deformation of Mg is strongly affected by its HCP crystal structure and it exhibits limited ductility (5%–8%) at room temperature (Gehrmann *et al.*, 2005). Low elastic modulus and the high price of magnesium are some of its additional limitations that hinder its marketing. The elastic modulus of magnesium (40–45 GPa) is almost like that of cortical bone (15–30 GPa).

Further, Mg has excellent biocompatibility and would not pose any toxicity to human cells (Parande *et al.*, 2020). Mg-based materials are beneficial for biomedical applications and have advantages over many biodegradable materials such as polymers, ceramics and bioactive glasses, particularly in load-bearing applications requiring higher strengths (Dyadyura and Sukhodub, 2017). Metallic implants like Ti-6Al-4V (113.8 GPa), 316L stainless steel (193 GPa) and Co-Cr alloy (220–240 GPa) have higher elastic modulus and if implanted inside the body would offer stress-shielding effects leading to additional surgery and patient morbidity (Kujur *et al.*, 2017). Magnesium as an implant would not offer any stress-shielding effects, and being biodegradable would dissolve inside the human body. But the poor corrosion resistance of magnesium impedes its clinical application. These limitations of magnesium can be circumvented with proper selection of (1) alloying elements; and (2) addition of inexpensive nanoparticulate (Kujur *et al.*, 2018; Wakeel *et al.*, 2018; Kujur *et al.*, 2019). Micron-size reinforcements, due to their larger size if embedded in the matrix, have a higher probability of containing fracture initiating defects, making particle fracture more prevalent. Further, micron-size reinforcements are generally seen to lead substantial reduction in the ductility of the magnesium matrix due to particle cracking and void formation at particle-matrix interface leading to accelerated failure. Addition of alloying elements is already known to improve the properties for the base matrix (Wakeel *et al.*, 2018). The inclusion of nanoparticulates in the base matrix would improve the properties of overall mechanical strength and ductility through dispersion strengthening without altering its density (Wakeel *et al.*, 2018). The composites with a small volume fraction of nano-size reinforcements have shown the results that are comparable or even sometimes superior to the composites reinforced with micron-size reinforcement at the same or higher volume fraction (Tjong, 2007; Casati and Vedani, 2014). Nanocomposites are lightweight materials which generally incorporate lower volume percentage of nanoparticles in their base matrix (Kujur *et al.*, 2018). Previous papers show the incorporation of oxides, nitrides, carbides, borides, hollow and amorphous nano-reinforcements to Mg and Mg-alloy (Gupta and Wong, 2015). The significant improvement in ductility and corrosion resistance can be seen in the published research works. Thus, to attempt the development of magnesium based nanocomposites is very much promising to serve in more extensive areas of structural and biomedical applications (Wong and Gupta, 2016).

Critically optimized techniques are opted to synthesize Mg-based nanocomposites. The typical processing methods used to synthesis magnesium metal nanocomposites are: (1) liquid state process: stir casting, ultrasonic assisted casting, infiltration process, disintegrated melt deposition (DMD), high pressure die casting; (2) solid state process: mechanical alloying, microwave sintering, bi-directional hybrid microwave sintering; (3) semi-solid state process: thixoprocessing; (4) friction stir processing (5) in-situ synthesis (Ceschini *et al.*, 2017a). Of attention is the liquid and semi-solid processing techniques, since they are potentially scalable to industrial level for the high-volume production of near-net-shape components (Ceschini *et al.*, 2017b). However, the general aim is to uniformly disperse the reinforcements and avoid agglomeration and achieve wettability throughout the matrix through a proper production route such that there won't be any detrimental effect on the mechanical properties. Particularly, disintegrated melt deposition (DMD) and powder metallurgy incorporating hybrid microwave sintering technique are two such methods where uniform dispersion of nano-reinforcements in the matrix is achievable. The hybrid microwave sintering is an energy-efficient and an environment-friendly technique. This method eliminates the usage of any inert gas or vacuum system for sintering, thus reducing the processing time significantly (Kumar *et al.*, 2018b). The Disintegrated Melt Deposition (DMD) technique is a modification of spray atomization and deposition technique. The DMD method brings together the cost-effectiveness of conventional casting and the scientific innovativeness and technological potential of the spray process (Parande *et al.*, 2018). Further, the introduction of secondary processing like extrusion after primary processing would give out homogenization of the distribution of reinforcements to improve the properties of composites (Parande *et al.*, 2018). The synthesis of the

nanocomposites of these two methods has shown significant improvement in the tensile strength, hardness, dimensional stability coupled with ductility and good toughness at both room temperature and high temperature (Mallick *et al.*, 2009).

This article focuses on magnesium-based nanocomposites synthesized using two methods: Powder metallurgy (P/M) assisted hybrid microwave sintering and disintegrated melt deposition (DMD) processing techniques. The tensile behavior with the inclusion of various reinforcements is compared as per the published data. This work also highlights the effect of strengthening mechanisms on the mechanical behavior (tensile yield strength (0.2% TYS), ultimate tensile strength (UTS), ductility and work of fracture (WOF)) of the nanocomposites to serve in wider areas of structural and biomedical applications.

Synthesis of Mg-Based Nanocomposites

The presented work shows nanocomposites prepared by (a) powder metallurgy (P/M) followed by hybrid microwave sintering and (b) disintegrated melt deposition (DMD) processing techniques and its significance.

Powder Metallurgy

The powder metallurgy route adapted in this study generally consists of blending, compaction, microwave sintering and hot extrusion. The nanopowders are initially blended in the mixing machine without the usage of balls at a high rotational speed with a limitation until 2 h to disperse the nanoparticles in the base matrix uniformly. The powder is compacted uniaxially to obtain green billets prior to microwave sintering. The secondary process, such as extrusion, is further employed to get rods of 8 mm in diameter.

Disintegrated Melt Deposition (DMD)

The disintegrated melt deposition (DMD) technique implicates the heating of magnesium chips/turnings and nanopowder to a superheated temperature in a graphite crucible. There is a continuous supply of inert gas to the crucible to avoid oxidation of the material. On reaching temperature above 650°C, a mild steel impeller is used to stir the molten slurry for 5 min at 450 rpm. This would ease the uniform dispersion of nanoparticles in the solid medium and maintain the temperature homogeneity. The base of crucible contains an orifice and the molten slurry is discharged through it. The two jet streams of argon gas are sprayed in the direction of melt stream before getting collected in a metallic substrate.

Tensile Properties for Mg-Based Nanocomposites

The experimental data for tensile analysis of Mg-based nanocomposites conducted at room temperature is represented by two different processing techniques. **Tables 1** and **2** denote the tensile yield strength (0.2% TYS), ultimate tensile strength (UTS), ductility and work of fracture (WOF) of the nanocomposites synthesized (a) powder metallurgy method followed by hybrid microwave sintering technique and (b) disintegrated melt deposition technique respectively. It is to be noted that the tensile strengths of the synthesized nanocomposites have been compared to the tensile strength of pure Mg taken from reference (Wong and Gupta, 2017) and (Hassan and Gupta, 2007a) respectively irrespective of their processing techniques to understand the percentage of improvement with nanoreinforcement addition in comparison to the base matrix.

The tensile properties for the Mg-based nanocomposites were determined as per ASTM E8M-01. It is clear from the results that with the addition of nanoparticles (metallic, ceramic and hybrid) in the base matrix, the 0.2% TYS, UTS and ductility (~ mostly) is seen to improve. However, the results also further show the increase or decrease in the tensile strength varying depending on the distribution and agglomeration of the nanoparticles embedded in the Mg matrix. Unlike micron size composites, the significant improvement in tensile strength displayed by the nanocomposites is noteworthy.

Table 1 presents the 0.2% tensile yield strength (TYS), ultimate tensile strength (UTS), ductility and work of fracture (WOF) for magnesium matrix composites embedded with micron-size and nano-size particles along with some of the commercially available alloys synthesized by powder metallurgy technique followed by microwave sintering. As seen from **Table 1**, Tun *et al.* included ZnO in pure Mg by powder metallurgy method incorporating hybrid microwave sintering followed by extrusion (Tun *et al.*, 2012). The tensile strength improved for pure Mg with an increasing amount of 0.5, 1.0 and 1.5 vol% of ZnO. Mg/1.0ZnO displayed the best 0.2% TYS (125 MPa), UTS (231 MPa) and ductility (17%) amongst Mg/0.5ZnO and Mg/1.5ZnO nanocomposites. The 0.2% TYS, UTS and ductility improved by 8%, 38% and 179% respectively in comparison to pure Mg. Similarly, with the increasing amount of 0.35, 0.5 and 1.0 vol% of SiC nanoparticle addition in Mg, the tensile property improved simultaneously (Wong and Gupta, 2006). Mg/1.0SiC displayed the best 0.2% TYS (157 MPa), UTS (203 MPa) and ductility (7.6%) amongst Mg/0.35SiC and Mg/0.5SiC nanocomposites. The 0.2% TYS, UTS and ductility for Mg/1.0SiC improved by 35%, 21% and 25% respectively in comparison to pure Mg. It is clear from **Table 1**, Mg/(0.7Y₂O₃ + 0.6Ni) nanocomposite showed the best improvements in the tensile strength property. The results also include the improvement of ductility and work of fracture in Mg/(0.7Y₂O₃ + 0.6Ni) as compared to pure Mg and other presented compositions (Tun and Gupta, 2009). The 0.2% TYS, UTS, ductility and WOF for Mg/(0.7Y₂O₃ + 0.6Ni) was 232 MPa, 272 MPa, 9.5% and 25.9 J/mm³ respectively. The 0.2% TYS, UTS, ductility and WOF improved

Table 1 Room temperature tensile properties of mg-based nanocomposites synthesized by powder metallurgy incorporating hybrid microwave method

Material	0.2% TYS (MPa)	UTS (MPa)	Ductility (%)	Work of fracture (MJ/m ³)

by 100%, 62%, 56% and 119%, respectively. Additionally, SiC particle in its micron size and nano-size has been added in pure Mg by powder metallurgy technique to understand its tensile nature. The yield strength and tensile strength improved for the micron-based composites, whereas there was significant reduction in ductility in comparison to pure Mg (Wong and Gupta, 2006). Whereas, for the Mg/SiC nanocomposites, the incorporation of nano reinforcements helped in improving the overall tensile properties of nanocomposites without reducing its ductility (Wong and Gupta, 2006).

Table 2 presents the 0.2% tensile yield strength (TYS), ultimate tensile strength (UTS), ductility and work of fracture (WOF) for magnesium matrix composites embedded with micron-size and nano-size particles along with some of the commercially available alloys synthesized by disintegrated melt deposition (DMD) technique. **Fig. 1** (data extracted from Hasan et al. Hassan and Gupta (2007a)) compared the room temperature tensile behavior of pure Mg and Mg/xY₂O₃ nanocomposites. As seen from **Fig. 1**, the tensile yield strength and ultimate tensile strength improved with the addition of 0.22, 0.66 and 1.11 vol% of Y₂O₃ nanoparticles. The

Fig. 1 Representative tensile stress-strain curves of magnesium and its nanocomposites. Data extracted from Hassan, S., Gupta, M., 2007a. Development of nano-Y₂O₃ containing magnesium nanocomposites using solidification processing. *Journal of Alloys and Compounds* 429 (1–2), 176–183.

maximum strength can be seen in the composite when 0.66 vol% Y₂O₃ was used in the Mg matrix. However, a good combination of ductility and strength is observed in Mg/0.22Y₂O₃ nanocomposite. In another study, Goh *et al.* (2006) incorporated 0.3, 1.3, 1.6, 2.0 wt % carbon nanotubes (CNTs) in Mg matrix by DMD technique which resulted in an improvement of 0.2% TYS, UTS, ductility. The 0.2% TYS (140 MPa), UTS (210 MPa) and ductility (13.5%) for Mg/1.3 wt%CNT improved by 44%, 21% and 82% respectively in comparison to pure Mg. The significant improvement in ductility for Mg/1.3 wt%CNT was due to the high activity of basal slip and the initiation of prismatic slip. The ductility was seen to be low for Mg/1.6CNT and Mg/2.0CNT in comparison to Mg/1.3CNT nanocomposite. The possible reason for the reduction of ductility may be due to the agglomeration and cluster formation of CNT nanoparticles in the Mg matrix. From Table 2, it is clear that Mg/0.66Y₂O₃ nanocomposite showed the best improvement in tensile strength property having 0.2% TYS (312 MPa) and UTS (318 MPa) with 222% and 84% increment respectively (Hassan and Gupta, 2007a). Mg/0.97TiC nanocomposite showed best improvement in ductility (22%) with 197% increment and Mg/1.98TiC nanocomposite showed best improvement in WOF (35.5 MJ/m³) with 220% increment in comparison to pure Mg (Meenashisundaram and Gupta, 2015). In Table 2, AZ31B, AZ31B/0.66 vol%Al₂O₃, AZ31B/1.50 vol%Al₂O₃ and AZ31B/1.50 vol%Al₂O₃ nanocomposite prepared by DMD technique has been compared with pure Mg (Nguyen and Gupta, 2008). The inclusion of nanoparticles in the base matrix improved the 0.2% TYS (144 MPa), UTS (214 MPa) and ductility (29.5%) for pure Mg by 48%, 24% and 299% respectively. It is evident that in the case of an alloy, the matrix is composed of multiple elements when mixed with nanoparticles would significantly improve the mechanical tensile behavior for pure Mg. The tensile testing results of the Mg composites reinforced with 1.1 vol% Al₂O₃ (particle size 1 μm) (Hassan and Gupta, 2006) and 1.1 vol% Al₂O₃ (particle size 50 nm) (Hassan and Gupta, 2004) synthesized by the DMD technique were presented. The 0.2% TYS and UTS improved for both the composition while the ductility was substantially affected for 1.1 vol% Al₂O₃ (1 μm). It can be inferred that micron size reinforcements boost the 0.2% TYS and UTS properties of pure Mg but at the expense of ductility. Hence, the introduction of nanoreinforcements is an appealing key to elevate the tensile properties with the rise in ductility at room temperature for Mg-based matrix. Additionally, the adaption of solid based and liquid based processing technique to synthesize the nanocomposites helps in achieving uniform distribution of nanoparticles in Mg and Mg-alloy cooperated in benefiting tensile results.

Table 3 represents the tensile strength, ductility and work of fracture of the pure Mg and Mg/Y₂O₃ nanocomposite at different temperatures (Mallick *et al.*, 2010). It can be seen that the nanocomposite samples exhibit more than 20% higher TYS (except 250°C) compared to pure Mg sample at room temperature and elevated temperatures. Similarly, the higher UTS is observed in the composite sample as compared to pure Mg sample and their percentage was increased at the elevated temperatures. The results also exposed that the presence of nano-Y₂O₃ as reinforcement improved room temperature ductility in Mg. The tensile strength (TYS and UTS) in both the pure Mg and composite gradually decreased with the increase of test temperature. The thermally activated plastic deformation may be responsible for the smooth dislocation movement which tends to increase the percentage of elongation at the expense of tensile strength. As the material becomes softer at elevated temperature, the percentage of elongation in pure Mg samples predominantly increased with the increase of temperatures. However, comparatively less increase in the percentage of elongation with the rise in temperature can be seen in the composites. The thermally stable Y₂O₃ limits the movement of the material flow. Further, the interfacial bonding between the nanoparticle and the matrix may weaken at high temperatures. At all the test temperatures, higher work to fracture is observed in the composite sample.

Table 3 High temperature tensile properties of Mg-based nanocomposites synthesized by powder metallurgy method

Temperature	Materials	0.2% TYS (MPa)	UTS (MPa)	Ductility (%)	Work of fracture (MJ/m ³)
25°C	Pure Mg	197 ± 7	130 ± 8.8	8.0 ± 2.3	15.2 ± 2.7
	Mg/0.22Y ₂ O ₃	244 ± 12 (+ 24%)	146 ± 9 (+ 12%)	14 ± 2.1 (+ 75%)	23.1 ± 3.1 (+ 52%)
100°C	Pure Mg	110 ± 12	81 ± 11	26.5 ± 2.7	27.0 ± 3.4
	Mg/0.22Y ₂ O ₃	150 ± 10 (+ 36%)	95 ± 7.3 (+ 17%)	27.7 ± 2.5 (+ 5%)	33.1 ± 2.4 (+ 23%)
150°C	Pure Mg	96 ± 6	56 ± 6.5	31 ± 2.8	21 ± 3.7
	Mg/0.22Y ₂ O ₃	129 ± 4 (+ 34%)	90 ± 6.1 (+ 61%)	32 ± 1.9 (+ 3%)	32 ± 2.8 (+ 52%)
200°C	Pure Mg	75 ± 4	44 ± 4.6	34.1 ± 3.4	18 ± 2.9
	Mg/0.22Y ₂ O ₃	92 ± 7 (+ 23%)	68 ± 4.8 (+ 55%)	33.5 ± 2.0 (− 2%)	25 ± 2.6 (+ 38%)
250°C	Pure Mg	62 ± 4	38 ± 3	34.5 ± 2.2	15 ± 2.6
	Mg/0.22Y ₂ O ₃	73 ± 6 (+ 18%)	61 ± 5 (+ 61%)	24.5 ± 2.3 (− 29%)	16 ± 4.0 (+ 7%)

Note: Mallick, A., Tun, K.S., Vedantam, S., Gupta, M., 2010. Mechanical characteristics of pure Mg and a Mg/Y₂O₃ nanocomposite in the 25–250°C temperature range. *Journal of Materials Science* 45 (11), 3058–3066.

Further, a significant contribution to increasing the 0.2% TYS, UTS and ductility can be attributed to strengthening mechanisms: (a) Orowan Strengthening (b) Hall-Petch Strengthening (c) Forest Strengthening (d) Taylor Strengthening and (e) Load Transfer Effect. The in-depth details of these strengthening mechanism are as follows:

Orowan Strengthening

The formation of dislocation loops with high work-hardening rates around the nanoparticles as a result of obstruction put forward by the nanoparticles to the dislocation movement is termed as Orowan strengthening (Meenashisundaram and Gupta, 2016). The Orowan Strengthening equation is represented by:

$$\sigma_{\text{Orowan}} = \frac{0.13Gb}{\lambda} \ln \frac{r}{b} \quad (1)$$

where G , b and r are the shear modulus of Mg (17.3 GPa), Burgers vector of Mg (3.21×10^{-10}) and average radius. λ denotes interparticle spacing between the nanoparticles within the matrix and is denoted by:

$$\lambda = d_p \left[\left(\frac{1}{2V_p} \right)^{\frac{1}{3}} - 1 \right] \quad (2)$$

where V_p is the volume fraction of the reinforcements and d_p is the diameter of nanoparticles. Zhang and Chen (2008) in their work suggested that for metal matrix nanocomposites with decreasing size and increasing volume fraction of nanoparticles, the relative contribution of Orowan strengthening effect increases. Additionally, for activation of Orowan strengthening, the processing techniques need to be controlled the interparticle spacing to prevent agglomeration of nanoparticles in the magnesium matrix. It is recommended to incorporate till 2.5 vol% of nanoparticles in the matrix considering the ability of the processing techniques to disperse the nanoparticles throughout the matrix (Meenashisundaram et al., 2015b). Tun et al. (2010) in their work prepared Mg/(0.7Y₂O₃ + 0.3Cu) and Mg/(0.7Y₂O₃ + 0.6Cu) hybrid nanocomposites and monolithic Mg samples by powder metallurgy technique. Due to the fine dispersion of both Y₂O₃ and Cu nanoparticles in Mg, a significant increase in strength was noticed (Hassan and Gupta, 2002c). As seen from Table 1, the decrease in strength for Mg/(0.7Y₂O₃ + 0.6Cu) is due to the coarsening of copper clusters/agglomerates leading to a reduction in the Orowan strengthening effect. Similarly, Kumar et al. (2018a) also showed owing to the presence of GNPs, and there is a formation of residual loops resulting in high strain, thus strengthening the Mg-3Al/0.1GNP nanocomposite.

Hall-Petch Strengthening

The performance of grain size in executing the strength of the nanocomposite is defined as Hall-Petch Strengthening. The grain size can be related inversely to the strength of the material. Thus, when the grain size reduces the strength of the nanocomposite increases (Meenashisundaram et al., 2015b). The Hall Petch-equation is represented by:

$$\sigma_{\text{Hall-Petch}} = KD^{-0.5} \quad (3)$$

where K is the Hall Petch coefficient of Mg (280 MPa $\mu\text{m}^{1/2}$) and D represents the average grain size of the Mg composites. Moreover, the Zener equation illustrates the relationship amid nanoparticle size, the volume fraction of the nanoparticles and grain size of the nanocomposites and is represented by:

$$d_m = \frac{4\alpha d_p}{3v_p} \quad (4)$$

Earlier results show the grain size reduced for Mg/1.98TiO₂ and Mg/2.5TiO₂ nanocomposites prepared by powder metallurgy route in comparison to pure Mg by 12% and 18% respectively (Meenashisundaram *et al.*, 2015b). Similarly, the grain size also significantly reduced for Mg/1.98TiO₂ and Mg/2.5TiO₂ prepared by disintegrated melt deposition technique in comparison to pure Mg by 40% and 18% respectively (Meenashisundaram *et al.*, 2015b). Owing to significant grain reduction displayed by Mg/1.98TiO₂ and Mg/2.5TiO₂ nanocomposites prepared by powder metallurgy route and disintegrated melt deposition technique, the nanocomposites showed higher Hall-Petch strengthening of around 58 MPa and 61 MPa respectively. The results displayed increase in strength for Mg/1.98TiO₂ and Mg/2.5TiO₂ nanocomposites owing to uniformly dispersed TiO₂ nanoparticles acted as nucleation sites during recrystallization and pinned the grain boundaries thus reducing the grain size for pure Mg.

Forest Strengthening

The mismatch in the coefficient of thermal expansion (CTE) between the nanoparticles and the metal matrix is accommodated during material cooling and straining by the formation of geometrically necessary dislocations (GNDs), thus contributing to the strength of the composite (Tun and Gupta, 2007). The Forest Strengthening established from the relaxation of thermal stresses between the matrix and nanoreinforcements is represented by:

$$\sigma_{CTE} = A \cdot M \cdot G \cdot b \cdot \rho_{th}^{0.5} \quad (5)$$

$$\rho_{th} = 12 \frac{\sqrt{2} \cdot \Delta\alpha \cdot \Delta T \cdot f}{b \cdot d \cdot (1 - f)} \quad (6)$$

where A , ρ_{th} , $\Delta\alpha$, and ΔT are constants characterizing the transparency of the dislocation forest for basal-basal interaction in Mg (0.2), dislocation density, the difference in CTE values between the nanoparticles and pure Mg, and temperature excursion that is chosen to be 250K (for all the nanocomposite) assuming that the dislocation generation begins at 550K corresponding to a stress-free homologous temperature of 0.6.

Habibi *et al.* (2013) showed in their work that the coefficient of thermal expansion for magnesium and B₄C nanoparticles was ($28.9 \times 10^{-6} \text{ K}^{-1}$) and ($5.0 \times 10^{-6} \text{ K}^{-1}$) respectively. This considerable difference in coefficient of thermal expansion values, a large amount of geometrically necessary dislocations is awaited to build up at Mg/B₄C interface. Generally, micron-based composites contribute more to forest strengthening owing to the inclusion of higher volume percentage of reinforcements. This is not the case with nanocomposites as the inclusion of nanoparticles with more than 2.5 vol% would lead to clustering and agglomeration that are eventually reducing the strength of the nanocomposite. Tun *et al.* (2010) showed room temperature tensile test for Mg/(0.7Y₂O₃ + 0.3Cu) nanocomposites indicated increased dislocation density due to mismatch on the coefficient of thermal expansion for magnesium ($28.9 \times 10^{-6} \text{ K}^{-1}$), Y₂O₃ ($7.6 \times 10^{-6} \text{ K}^{-1}$) and copper ($18.3 \times 10^{-6} \text{ K}^{-1}$). However, with an increase in the volume percentage of Cu nanoparticles for Mg/(0.7Y₂O₃ + 0.6Cu) and Mg/(0.7Y₂O₃ + 0.6Cu) nanocomposites the tensile strength is seen to decrease gradually. The decrease in strength was attributed to increasing agglomeration of metallic Cu and Y₂O₃ nanoparticles.

Taylor Strengthening

The mismatch between the elastic modulus of the nanoparticle and magnesium matrix leading to the formation of geometrically necessary dislocations (GNDs) is termed as Taylor Strengthening. Taylor Strengthening is represented by:

$$\sigma_{EM} = \sqrt{3} \cdot \alpha \cdot G \cdot b \cdot \sqrt{\rho_{EM}} \quad (7)$$

$$\rho_{EM} = \frac{6V_p}{\pi d^3} \quad (8)$$

where α and ρ_{EM} are the constant (0.5) and dislocation density resulting from modulus mismatch.

Kumar *et al.* (2018a) reported an increase in dislocation density that due to misfit in elastic modulus values of GNPs (0.7–1.2 TPa), magnesium (40–45 GPa) and aluminum (69.6 GPa) respectively for Mg-3Al/0.1GNP nanocomposite. Similarly, Tun and Gupta (2007) in their work reported the difference of elastic modulus for magnesium (44.7 GPa) and yttria (177.6 GPa) and the higher volume fraction of reinforcement it would lead to higher dislocation density in the matrix. It can be inferred that the presence of nanoparticles causes incompatibility in deformation in the matrix through the geometrically necessary dislocations stored near the surfaces of particles. However, the Taylor strengthening doesn't contribute much to the nanocomposites in comparison to other strengthening mechanisms and hence is considered negligible.

Load Transfer Effect

The strengthening resulting from transferring of load from the soft matrix to the uniformly distributed hard and stiff nanoparticles under an external load thus contributing to the strength of the matrix is termed as load transfer effect (Zhong *et al.*, 2007). The Load Transfer Effect is represented by:

$$\sigma_{LT} = 0.5v_p\sigma_{Mg} \quad (9)$$

where σ_{LT} is the experimental 0.2% tensile yield strength (0.2% TYS) of pure Mg.

The transfer of load from the Mg matrix to the stiffer nanoparticles rely on the interfacial bonding between the matrix and nano-reinforcement. The FESEM micrographs, as shown in Fig. 2(a), indicates good interfacial bonding between the Mg-3Al alloy and GNP. Few cluster of GNP can be seen in Fig. 2(b). The hard nanoreinforcement restrict the grain growth by arresting the grain boundary migration. Furthermore, the intermetallic hard particles ($Mg_{17}Al_{12}$) that was formed during the development of an alloy of Mg and Al eventually improved the strength of nanocomposites by reducing the grain size (Mallick *et al.*, 2009). Since the incorporation of nano-reinforcements is in a lower amount, the load-bearing contribution for the nanocomposites can be considered negligible in comparison to micron-based composites. For example, magnesium reinforced with 10 vol% Ni50Ti50 and 40 vol% Ni50Ti50 exhibited a load transfer effect of 3.75 MPa and 15 MPa respectively (Meenashisundaram and Gupta, 2016).

The improvement in ductility for the magnesium matrix can be attributed to:

- (a) Presence of fine nanoparticulates; (b) Grain refinement; (c) Non-basal slip system or cross slip.

Fig. 2 The micrographs of Mg-3Al/0.5 CNT showing (a) interfacial integrity between CNT nano particle and Mg-3Al alloy matrix and (2) the presence of GNP cluster.

Fig. 3 Tensile fractograph confirming (a) brittle fracture in pure Mg and (b) mixed mode fracture with few dimples like features in Mg-2 wt% Y_2O_3 nanocomposite.

Fig. 4 X-ray diffractograms of pure Mg and Mg-ZnO nanocomposites were taken (a) along the cross-section of the samples and (b) along the longitudinal direction of the samples from Sankaranarayanan *et al.* Reproduced from Sankaranarayanan, S., Nayak, U.P., Sabat, R.K., *et al.*, 2014a. Nano-ZnO particle addition to monolithic magnesium for enhanced tensile and compressive response. *Journal of Alloys and Compounds* 615, 211–219.

The fine nanoparticulates in magnesium matrix:

- (1) Add locations to clear cleavage crack to an advancing crack front to dissipate stress concentration,
- (2) Alter the local effective stress from plane strain to plane stress state about the crack tip.

Mallick *et al.* (2010) reported the grain refinement in Mg/2 wt%Y₂O₃ nanocomposite which exhibited grain size of around 18 μm in comparison to the grain size of pure Mg (20 μm). The higher value of elastic modulus of the reinforcement compared to pure Mg significantly increase dislocation density. Further, this increase σ_{EM} and σ_{CTE} values which leading to increase the tensile strength in the composite. The reduction of grain size and the presence of dimples on fracture surfaces are also indicative of the improved tensile strength and ductility. Further, the tensile fractographs (Fig. 3(b)) confirmed the activation of non-basal slip systems. Additionally, there was a formation of wavy slip indicating homogeneous deformation and optimum ductility for Mg/2 wt%Y₂O₃ nanocomposite (Tun *et al.*, 2010).

This can primarily be attributed to: (a) the activation of non-basal slip system (Seetharaman *et al.*, 2013) and (b) tendency of Y₂O₃ particulates to enhance cross-slip (Tun *et al.*, 2013). In past studies, similar observations were made when Ti (Parande *et al.*, 2020), nanosize Al₂O₃ (Parande *et al.*, 2017) and carbon nanotube (Dyadyura and Sukhodub, 2017) were used as reinforcements. In past studies, it was also indicated that both precipitation and dispersion have the ability to enhance cross-slip tendency (Tun *et al.*, 2013).

Usually, the uniformly dispersed nanoparticles reduced the grain size of Mg by pinning the grain boundaries. These dispersed particles are supposed to add locations to clear cleavage crack ahead of an advancing crack front and expedite to weaken the stress concentration at the crack front. The fractographs confirmed the presence of intergranular cracks promoting an increase in ductility. Generally, Mg has a strong basal structure and its alignment of the basal planes (0002) parallel to the extrusion direction leads to poor ductility. With the incorporation of nano-reinforcements, the changes in crystallographic texture, as confirmed by X-Ray

Fig. 5 Dislocation structures in Mg-3Al/0.3GO alloy-nanocomposite.

Fig. 6 Proposed schmid mechanism for mechanical property enhancement from Sankaranarayanan *et al.* Reproduced from Sankaranarayanan, S., Nayak, U.P., Sabat, R.K., *et al.*, 2014a. Nano-ZnO particle addition to monolithic magnesium for enhanced tensile and compressive response. Journal of Alloys and Compounds 615, 211–219.

diffraction studies, suggest the tilting of basal planes at an angle and not parallel to the extrusion direction. An example is in the case for Mg/ZnO nanocomposites synthesized by a disintegrated melt deposition method; the composites exhibited better fracture strain as compared to pure Mg (Sankaranarayanan *et al.*, 2014a). The X-ray diffractograms (Fig. 4) for Mg/ $x\%$ ZnO ($x = 0.16, 0.48, 0.8$) taken parallel to the extrusion direction indicated the highest intensity for $2\theta = 36^\circ$ corresponding to pyramidal plane conforming texture randomization.

The TEM observation of Mg-3%Al/0.3%GO alloy composite (Fig. 5) shows the presence of a dislocation network and the twins. This result reveals that GOs boosted in tilting of the basal plane from the extrusion direction and activating non-basal cross-slips. Similarly, Goh *et al.* (2008) confirmed in their work through TEM observations that CNTs boosted in tilting of the basal at an angle of 20° from the extrusion direction and activating non-basal cross-slips.

Further, to understand the texture effects on ductility enhancement through slip assisted hardening behavior, the Schmid factor (Fig. 6) was proposed by Sankaranarayanan *et al.* (2014a). Schmid factor is the measure of volume fraction of grains contributing to each slip system suggesting more dislocation activity was carried out along basal planes. This in turn would increase the apparent critical resolved shear stress (CRSS) value in the basal plane for further dislocation activity. Additionally, the nanoparticles interactions with the dislocations aid in boosting the hardening behavior and lead to increment in CRSS value closer to that of the prismatic slip system.

Fig. 7 Tensile fracture surface of (a) pure Mg, (b) Mg/0.35B₄C; (c) Mg/1.04B₄C; (d) Mg/1.74B₄C; (e) presence of slip in basal plane and (f) combined effect of basal and non-basal slip in Mg/1.04B₄C nanocomposite from Sankaranarayanan *et al.* Reproduced from Sankaranarayanan, S., Sabat, R.K., Jayalakshmi, S., Suwas, S., Gupta, M., 2014b. Effect of nanoscale boron carbide particle addition on the microstructural evolution and mechanical response of pure magnesium. *Materials & Design* 2014 (56), 428–436.

Also, the work of fracture (WOF) was seen to improve with the addition of nanoparticles. In the case of Mg/0.5Al nanocomposites the WOF improved by 119% (Tun and Gupta, 2007). The significant improvement in the work of fracture is due to simultaneous improvement in the strength and ductility of the nanocomposite.

From the fracture analysis, Fig. 7 (a) shows Magnesium's inability to deform homogeneously under uniaxial tensile loading was evident through the presence of cleavage steps and small plastic deformation with reasonably sharp fractures surfaces. Fig. 7 (b)-(d) show ductile fracture owing to plastic deformation. Further, there is a combined effect of basal and non-basal slip as imposed by uniformly dispersed B₄C nanoparticles on pure Mg (Sankaranarayanan *et al.*, 2014b).

Introduction

Transportation sector (land, air, and water) is the main sector where lightweight metallic materials are actively sought to reduce fossil fuel consumption. In this context, metal matrix composites (MMCs) are receiving increased consideration primarily for reducing the carbon signature and ever increasing global warming (Venci and Rac, 2004; Chawla and Chawla, 2006).

In the 21st century, high strength, lightweight and energy-efficient materials have received extensive attention, since the problems of energy and environment are major concern areas. In order to circumvent these issues, researchers and engineers are striving to develop new engineering materials such as metal based nanocomposites that can satisfy both global and engineers' concerns (Fig. 1). These modern engineering materials are expected to find wide spectrum of applications in multiple engineering sectors such as aerospace, defense, automobile and electronic industries (Mathew *et al.*, 2018).

The performance and efficiency of these applications can be increased largely by the application of modern engineering materials: composites. Metal matrix composites are a unique class of materials that are targeted to cater to ever increasing stringent service conditions to improve reliability and product/device lifetime. Hence, technological developments in various fields depend on the advances made in the field of materials and in a way, it is one of the key factors that ultimately decide the extent of perfection and sophistication required by modern technology.

Metal matrix composites have the capability to integrate the unique capabilities of judiciously selected reinforcement in the form of particles, whiskers or short/continuous fibers with that of the matrix (Ibrahim *et al.*, 1991; Lloyd, 1994). In light metal matrix composites, Al, Mg, and Ti are commonly used as base metallic matrix and ceramic particles (oxides, carbides, borides, and nitrides) are generally used as the reinforcing phases. The main role of the reinforcement is to increase the strength, stiffness and thermal capabilities while reducing the thermal expansion coefficient of the resulting MMC. However, the choice of an appropriate matrix needs careful consideration to avoid undesirable chemical reactions between the matrix and the reinforcement (Ma *et al.*, 1996; Kang and Chan, 2004).

Nanocomposites, a variation of conventional MMCs, are largely targeted for automotive and aerospace industries due to their ability to resist high temperatures and pressures. Recently, metal matrix nanocomposites (MMNCs) have become more attractive in various applications due to their superior mechanical properties when compared to conventional MMCs containing micro-particles. Nanocomposites are composite material that display at least one of its matrix feature such as grain size or reinforcement length scale in nanometric zone that is typically less than 100 nm (Rino *et al.*, 2012; Abbass and Fouad, 2014; Babalola *et al.*, 2014).

Fig. 1 Metal matrix nanocomposites for different applications.

Aluminum is one of the lightest structural metallic material (with a density of 2.7 gm/cm^3 , about a third that of steel) that is widely available and has attracted much attention for weight-critical applications in automotive, aerospace, space, sports and electronic industries, due to its high ductility, appreciable corrosion resistance and attractive strength/weight ratio (Ipek, 2005; Topcu *et al.*, 2009; El-Labban *et al.*, 2014). Depending on the desired application, both micron and nano length scale particles can be used as a reinforcing phase in the metal matrix (Fogagnolo *et al.*, 2003). Nanoparticles as reinforcement in metal matrix composites have been progressively replacing other types of reinforcement such as nanofibers, nanowhiskers, or nanoplatelets due their ease of manufacture and comparatively low cost. The most commonly used types of nanoparticles are SiC, TiC, B_4C , Si_3N_4 , SiO_2 , AlN, Al_2O_3 , graphene nanoparticles, amongst others (Karbalaee Akbari *et al.*, 2013; Pradhan *et al.*, 2015; Bisht *et al.*, 2017; Issa *et al.*, 2017; Matli *et al.*, 2017b; Reddy *et al.*, 2017; Ubaid *et al.*, 2017; Reddy *et al.*, 2018a).

Aluminum alloys have been developed progressively over last 100 years and utilized significantly in engineering applications over last 40 years. They exhibit wide spectrum of properties and cater to a wide array of applications. Integrating these aluminum alloys with reinforcements at nanolength scale provide the unlimited possibility of tailoring their end properties for even a wider array of applications and for more abusive conditions. This unique ability of end application based tailoring of properties and other attributes like ease of manufacturing, high strength, low coefficient of thermal expansion, wear resistance, corrosion resistance, durability, adaptability, and cost of effectiveness, etc., have been catalytic in attracting the attention of many industries towards using aluminum matrix nanocomposites in several engineering application (Fig. 2) (Rawal, 2001; Miracle, 2005).

Several manufacturing methods have been used to produce Al-based nanocomposites and these include powder metallurgy (Zakaria, 2014), conventional casting (Singh *et al.*, 2015) and conventional hot extrusion (El-Kady and Fathy, 2014). The main disadvantage of the conventionally processed materials is a lack of homogeneity in the dispersion of the particles and poor interfacial integrity between the matrix and the particles. However, research and development on compositional adjustment of nanocomposites and the methods to make them are still ongoing not only to overcome these limitations but also to realize overall superior microstructural characteristics.

Generally, the powder metallurgy (PM) process is widely known to be an excellent metallic material synthesis technique including that for composites (Reddy *et al.*, 2017). It usually involves mixing of powders of the matrix elements with the reinforcing particles, followed by compaction and solid-state sintering. Most powder consolidation and other processing steps including sintering are carried out below the matrix solidus temperature.

Fig. 2 Applications of aluminum nanocomposites in various sectors.

In addition to traditionally used sintering, microwave sintering using a 2.45 GHz microwave furnace is also successfully and economically used to sinter the compacted materials. The frequency of these microwave electromagnetic waves ranges from 400 MHz to 60 GHz. Microwave susceptors are normally used to aid the sintering process as they rapidly couple with microwaves and enable rapid heating of the compacted powder to be sintered. These susceptors are often made of silicon carbide. The microwave heating presents a potential economical sintering process with shortened processing time for the materials leading to cost, time and energy savings. This method is expected to overcome many of the shortcomings of the conventional sintering process such as maintaining comparatively refined microstructure (Yang *et al.*, 2004; Matli *et al.*, 2016).

The sintered composites are sometimes subjected to secondary processing such as extrusion to reduce porosity, refine the microstructure, and to homogenize the distribution of the reinforcement, all of which tend to improve the mechanical properties of materials which involve high temperatures and large strain deformation (Suresh *et al.*, 1993; Clyne and Withers, 1995).

In view of tremendous potential of nanocomposites in engineering applications, this article attempts to provide a comprehensive overview of the techniques used for manufacturing metal matrix nanocomposites with particular emphasis on mechanical properties including hardness and tensile properties.

Processing Techniques

Among the many factors, the properties of the composites critically depend on the effectiveness of the synthesis techniques to disperse the reinforcements uniformly within the metallic matrix. Metal matrix nanocomposites are typically synthesized using either solid-based processing (powder metallurgy) or liquid-based techniques (sand casting, permanent mold casting, disintegrated melt deposition, pressure infiltration, squeeze casting etc.). Technical difficulties related to liquid state processing include residual porosity, reinforcement segregation, and clustering and poor interfacial bonding which adversely affect the properties of the composites. Powder metallurgy processing can circumvent many of these drawbacks (heterogeneity in microstructure and reinforcement distribution) and particularly limit the undesired reaction between the metallic matrix and reinforcement because of lower temperatures (lower than melting point of base matrix) utilized during various processing steps. Hence, the discussion in subsequent sections will be limited to powder metallurgy technique incorporating hybrid microwave sintering that was developed by our research group. Detailed information on this processing technique can be found in open literature (Reddy *et al.*, 2018b).

Powder metallurgy technique assisted with hybrid microwave sintering (PM + MW).

Powder metallurgy process is divided into several steps including powder preparation, mixing, consolidation and sintering. Fig. 3 presents a general flow chart for the powder metallurgy process.

Typically matrix in powder form and nano-size reinforcements are carefully weighed and blended to obtain homogeneously mixed powders. These powders are compacted (uniaxially/hot isostatic pressing) to obtain a green compact billets. This green compact is further sintered for a pre-determined time using a conventional furnace or a microwave furnace.

After primary processing, billets of microwave sintered Al and Al composites are hot worked using methods such as extrusion, forging and rolling. Depending on the materials system, secondary processing can be done either below or above recrystallization temperature. Fig. 3 shows a typical processing methodology for Al-BN metal matrix nanocomposites. Characterization studies are typically carried out either on sintered or secondary processed samples using international standards.

Properties of Al-Based Metal Matrix Nanocomposites

Aluminum can be reinforced with suitable reinforcement to improve its properties such as specific strength, stiffness, hardness, and wear resistance. Pure aluminum has been studied extensively because of its low density, good machinability, high ductility, good thermal stability, and other salient properties. The use of aluminum has been growing in the industry as a material for several versatile and typically weight critical applications. Commonly used nanoreinforcements such as Al_2O_3 , B_4C , SiC, BN, TiC, SiO_2 , etc., have noticeably influenced the structural, physical and mechanical properties of Al-based nanocomposites.

Reddy *et al.* (2018b) investigated BN nanoparticles reinforced Al metal matrix composites with volume fraction ranging from 0 to 1.5 vol%. These composites were synthesized using the blend-press-sinter powder metallurgy technique followed by hot extrusion. The experimental results showed that the density decreases while porosity increases with the addition of BN nanoparticles (Fig. 4). This can be ascribed to the lower density of nanosized boron nitride particles (2.1 g/cc) when compared to pure aluminum (2.7 g/cc).

Toozandehjani *et al.* (2017) synthesized Al-5 wt% Al_2O_3 nanocomposite using ball milling assisted powder metallurgy technique. Aluminum and spherical nano alumina (Al_2O_3) particles were ball milled in planetary ball milling machine at 300 rpm with 8:1 ball to powder ratio for different milling times ranging from 0.5 to 12 h. The ball milled powder mixtures were uniaxially compacted at a pressure of 150 MPa and sintered at 580°C for 45 min to produce nanocomposites. The results of X-ray diffraction studies are shown in Fig. 5. The fewer and low intensity peaks of alumina may be attributed to its low volume fraction (Prabhu *et al.*, 2006).

Reddy *et al.* (2017) investigated the effect of SiC content (0.3, 0.5, 1.0, and 1.5 vol%) on the microstructural characteristics of Al nanocomposites fabricated by microwave sintering followed by hot extrusion. Fig. 6 shows the XRD patterns of Al-SiC nanocomposites. Results revealed the presence of SiC in the Al matrix with no signs of the formation of other intermetallic phases.

Progress in Natural Science: Materials International 27 (5), 606–614.

Fig. 7 shows optical micrographs of aluminum nanocomposites containing Al₂O₃ and SiC nanoparticulates. The authors (Mahmoud *et al.*, 2012) reported an increase in the agglomeration of nanoparticulates when the volume fraction of the nanoparticulates dispersed into the Al matrix is increased. The Al-SiC nanocomposites exhibited more agglomeration percent when compared with the Al-Al₂O₃ nanocomposites. The agglomerations size in Al-SiC nanocomposites was found to vary between 0.5 and 10 μm .

Issa *et al.* (2017) reported the fabrication and mechanical properties of SiO₂ nanoparticles (1, 2, and 3 wt%) reinforced aluminum matrix composites using powder metallurgy and hot extrusion processes. The SEM microstructural examination of extruded Al-SiO₂ composite samples is shown in **Fig. 8**. Results revealed non-uniform distribution of SiO₂ nanoparticles that was particularly attributed to their nanometric size. To note that dispersion of nanoparticles is always challenging due to their large surface area that promotes clustering.

Matli *et al.* (2017b) fabricated Al-Si₃N₄ (0, 5, 1, and 1.5 vol%) nanocomposites using the powder metallurgy method involving microwave sintering technique followed by hot extrusion. The authors reported homogeneous distribution of Si₃N₄ nanoparticles in the Al matrix validated through the elemental distribution map secured through SEM/EDS set-up. EDS analyses in **Fig. 9**, confirmed the presence of Si and N phases and were in good agreement with the distribution of Si₃N₄ in the Al matrix.

Li *et al.* (2019) investigated the mechanical behavior of 10 vol% SiC/Al nanocomposites. The nanocomposites were synthesized by hot pressure sintering and hot extrusion techniques. TEM micrographs in **Fig. 10** show morphology of the Al grains in extruded 10 vol% SiC/Al nanocomposite. The distribution of nano-sized SiC particle reinforcement in matrix was good due to

Fig. 7 Optical micrographs of (a) Al-5 vol% Al₂O₃ and (b) Al-5 vol% SiC nanocomposites. Reproduced from Mahmoud, T.S., *et al.*, 2012. Corrosion behaviour of Al/SiC and Al/Al₂O₃ nanocomposites. *Materials Research* 15 (6), 903–910.

superior wettability between matrix and reinforcement. The composites exhibited superior tensile strength with the addition of SiC owing to superior grain boundary strengthening. Hence, they claimed their method to be one of the most economical and efficient to produce Al-SiC nanocomposites.

Various mechanical properties of Al based nanocomposites improved, including the microhardness, tensile strength, depending upon the choice of reinforcement (type, particle size, and content) in the matrix. [Table 1](#) summarizes mechanical response of a number of aluminum based nanocomposite systems prepared using different processing methodologies. It was observed that microhardness, yield strength, and tensile strength tend to increase, and ductility decreases with the increasing volume fraction of nanosized particulates. Tensile properties such as yield strength and tensile strength generally tend to improve with decreasing particle size for a given volume fraction of reinforcement.

Table 1 Hardness and tensile properties of Al-based nanocomposites

Materials	Synthesis route	Particle size	Hardness (Hv)	Tensile properties		
				0.2% TYS (MPa)	UTS (MPa)	Ductility (%)
Pure Al	Microwave sintering + Hot extrusion (Matli <i>et al.</i> , 2017b)	15–30 nm	37 ± 3	105 ± 2	116 ± 4	13.6 ± 0.3
Al – 0.5 vol% Si ₃ N ₄			58 ± 4	124 ± 4	139 ± 7	11.2 ± 0.3
Al – 1.0 vol% Si ₃ N ₄			72 ± 3	140 ± 5	163 ± 5	9.3 ± 0.5
Al – 1.5 vol% Si ₃ N ₄			101 ± 5	165 ± 8	191 ± 6	7.2 ± 0.4
Al–0.3 vol% SiC	Microwave sintering + Hot extrusion (Reddy <i>et al.</i> , 2017)	15 nm	49 ± 6	117 ± 2	130 ± 3	11.9 ± 1.3
Al–0.5 vol% SiC			56 ± 3	125 ± 3	144 ± 7	9.8 ± 0.8
Al–1.0 vol% SiC			73 ± 4	140 ± 5	160 ± 9	8.6 ± 0.6
Al–1.5 vol% SiC			82 ± 4	158 ± 9	178 ± 6	7.3 ± 0.9
Al – 0.5 vol% TiC	Microwave sintering + Hot extrusion (Reddy <i>et al.</i> , 2018a)	50 nm	46 ± 3	117 ± 5	135 ± 4	10.2 ± 0.3
Al – 1.0 vol% TiC			79 ± 5	128 ± 3	151 ± 6	8.1 ± 0.2
Al – 1.5 vol% TiC			94 ± 6	151 ± 2	186 ± 3	7.2 ± 0.3
Al – 0.5 vol% B ₄ C	MWS + Hot extrusion (Ubaid <i>et al.</i> , 2017)	10 nm	78.85	132.68	156.9	10.6
Al – 1.0 vol% B ₄ C			135.56	173.14	194.41	7.7
Pure Al	Powder metallurgy + hot extrusion (Issa <i>et al.</i> , 2017)	30–50 nm	27.6	78	119	0.28
Al – 1 wt% SiO ₂			39.15	85	148.5	0.26
Al – 2 wt% SiO ₂			38.7	95	142.77	0.12
Al – 3 wt% SiO ₂			38.7	100	136.68	0.09
Al – 0.5 vol% BN	Microwave sintering + hot extrusion (Reddy <i>et al.</i> , 2018b)	30–50 nm	48 ± 4	119 ± 6	127 ± 3	10.4 ± 0.2
Al – 1.0 vol% BN			67 ± 3	126 ± 3	137 ± 6	8.2 ± 0.5
Al – 1.5 vol% BN			88 ± 4	144 ± 2	158 ± 4	6.9 ± 0.4
Pure Al	Stir casting technique (Pradhan <i>et al.</i> , 2016)	–	56 ± 2	62.6	123.1	–
Al-Fe aluminides			79 ± 4	95.8	197.5	–
Pure Al	Ultrasound assisted stirring (Ma <i>et al.</i> , 2017)	–	40.2	111	127	13.5
Al – 1 wt% SiC			50.4	132	157	8.8
Al – 2 wt% SiC			53.8	135	163	5.9
Al – 3 wt% SiC			56.1	142	162	4.7
Pure Al	SPS + hot extrusion (Zeng <i>et al.</i> , 2018)	20 nm	22	52	85	0.17
Al – 5 vol% CNT			52	105	194	0.11
Pure Al	Accumulative Roll Bonding (ARB) (Ramkumar and Natarajan, 2019)	30 nm	44	–	52	–
Al – 0.75 wt% TiO ₂			65	–	96	–
Al – 1.5 wt% TiO ₂			83	–	163	–
Al – 2.25 wt% TiO ₂			97	–	210	–
Al – 3 wt% TiO ₂			116	–	265	–
Pure Al	Spark plasma sintering (Bisht <i>et al.</i> , 2017)	6–8 nm	–	55	68	2.6
Al – 0.5 wt% GNP			–	51	80	1.6
Al – 1 wt% GNP			–	66	103	1.4
Al – 3 wt% GNP			–	37	44	0.5
Al – 5 wt% GNP			–	22	27	0.02

Matli *et al.* (2017a) used the powder metallurgy technique to fabricate Al-SiC, Al-Si₃N₄, and Al-Al₂O₃ composites. An example of the enhancement in microhardness in the case of microwave-assisted hot extruded Al-SiC, Al-Si₃N₄, and Al-Al₂O₃ composites can be seen in Fig. 11. The experimental results also showed that the highest hardness was obtained for 15-nm Si₃N₄ reinforced aluminum nanocomposites when compared to 35-nm (SiC) reinforced aluminum illustrating also the effect of size of nanoreinforcement.

Isa *et al.* studied the tensile properties of amorphous nano SiO_2/Al composites prepared by powder metallurgy and extrusion. Results showed that with the addition of 1 wt% amorphous silica nanoparticle to Al, the tensile strength and hardness increased by about 24.8% and 41.8%, respectively (Issa *et al.*, 2017).

The influence of BN nanoparticles (0.5, 1.5, 3, 4.5, 6, and 7.5 wt%) content on the tensile strength of Al-BN nanocomposites was investigated by Pradhan *et al.* (2016). It was observed that the addition of 4.5 wt% BNNP reinforcements to aluminum matrix leads to an $\sim 50\%$ improvement in tensile strength when compared to unreinforced aluminum. Further, the composites with 4.5 wt% BNNP showed 190% higher yield stress than that of pure aluminum when it was tested at 300°C .

Reddy *et al.* (2017) studied the room temperature tensile properties of SiC reinforced aluminum matrix nanocomposites. Silicon carbide particles with an average particle size of ~ 15 nm were used in the study. The best combination of yield and tensile strengths was observed in the case of Al-1.5 vol% SiC, which are $\sim 51\%$ and $\sim 49\%$ greater than the pure Al. The microwave-hot extruded Al-SiC nanocomposites showed considerable improvement in hardness and tensile strength in comparison with the stir cast processed materials (Table 1).

Reddy *et al.* (2018a), in another study, reinforced TiC particles (50 nm) to pure aluminum using microwave sintering and hot extrusion to improve their mechanical properties. The obtained room temperature tensile engineering stress-strain relationship of the developed Al and Al-TiC are presented in Fig. 12. The results indicated that the incorporation of 1.5 vol% of TiC nanoparticles to Al led to an increase of 41% in Young's modulus, and 56.3% in UTS, while ductility decreased by $\sim 42\%$.

Karbalaee Akbari *et al.* (2013) used a novel approach to fabricate A356-based nanocomposites containing Al_2O_3 nanoparticles. The Al_2O_3 nanoparticles were ball milled for 1, 4, 8, 16, and 24 h. Stir casting method was used for processing the

Fig. 11 Hardness of aluminum metal matrix composites. Reproduced from Matli, P.R., *et al.*, 2017a. Development of metal matrix composites using microwave sintering technique. In: Sintering of Functional Materials. IntechOpen.

Fig. 12 (a) Tensile stress-strain curves of the Al-TiC nanocomposites and (b) variations of elongation, strength (yield & tensile) of the composites with different amounts of TiC. Reproduced from Reddy, M.P., *et al.*, 2018a. Enhancing thermal and mechanical response of aluminum using nanolength scale TiC ceramic reinforcement. *Ceramics International* 44 (8), 9247–9254.

nanocomposites. A considerably uniform distribution of Al_2O_3 nanoparticles was observed in the composites. However, the tensile strength and hardness of the nanocomposites decreased with an increase in ball milling time of Al_2O_3 nanoparticles.

Steinman *et al.* (2018) studied the microstructure and interface characteristics of BN, AlB_2 , and AlN particles (0, 1, 3, 5, and 7 wt%) containing aluminum matrix nanocomposites. These nanocomposites were fabricated via ball milling followed by novel spark plasma sintering. The room and elevated (500°C) temperature tensile tests results showed an increase in the case of Al-BN composites with the progressive addition of the secondary BN phase. The maximum strength of 170 MPa was observed for the Al-BN composite. The Al- AlB_2 sample showed a value of 80 MPa, which is still 60% higher than that of Al, whereas the Al-AlN samples exhibited 30 MPa strength which is lower than that of pure Al (42 MPa).

Pradhan *et al.* (2016) studied the Fe-aluminide particles reinforced Al composites produced by stir casting method. Microstructural characterization of Al-Fe aluminide composites revealed the formation of intermetallic phase $\text{Al}_{13}\text{Fe}_4$. The incorporation of Fe-aluminides particles into pure Al matrix resulted in the progressive improvement of ultimate tensile strength and 0.2% yield strength values in all composites. The mechanical properties of the Al-Fe aluminide composites are shown in Table 1.

Kwon *et al.* (2009) reported the synthesis and mechanical properties of aluminum/carbon nanotube (CNT) composites using spark plasma sintering (SPS) followed by hot extrusion. The distribution of carbon nanotubes in the matrix was improved by the superior wettability between reinforcement and aluminum. Results of microhardness measurements revealed that increasing the volume fraction of CNTs leads to an increase in the hardness of aluminum nanocomposites. It was reported that the slight addition of 5 vol% CNTs to aluminum leads to a 200% improvement in the ultimate tensile strength (194 MPa) compared to pure aluminum. The combination of SPS and hot extrusion method exhibit a good level of mechanical properties with carbon nanotube. However, this technique is expensive and has its processing limitations.

Bisht *et al.* (2017) synthesized Al-GNP nanocomposite with GNP average particle size and thickness of 15 μm and 6–8 nm, respectively. The composites were synthesized by spark plasma sintering technique. Effect of different amount of GNPs was evaluated. XRD analysis, scanning/transmission electron microscopy confirmed the presence of graphene particles in the aluminum matrix. The hardness increased by 21.4%, yield strength and ultimate tensile strength increased by 84.5% and 54.8%, respectively, by adding only 1.0 wt% of graphene nanoplatelets (GNPs) to the matrix (Fig. 13).

The effect of nano Al_2O_3 particles on the mechanical and microstructure properties of the Al- Al_2O_3 nanocomposites was investigated by Ramkumar and Natarajan (2019). They reported that the yield strength and tensile strength of 5 wt% Al_2O_3 /Al nanocomposite showed an increase of about ~23% and 26%, respectively, when compared to the Al matrix.

SEM micrograph of fracture surfaces of failed tensile pure aluminum and Al-1.5 vol% TiC nanocomposite samples are shown in Fig. 14. The center part of fracture surfaces exhibited predominantly ductile failure which contained fine dimples, while the lips contained oval dimples and sheared faces. Fig. 14(b) shows a small and large dimples. Large dimples were found to contain clusters of TiC nanoparticles.

Future Work

The results presented in the previous sections indicate that substantial research has been conducted to develop aluminum based nanocomposites. However, there is still a large area for improvements which could be topics for further research and development activities on aluminum-based nanocomposites. Very few investigations are made on the understanding of the strengthening effect of nanometric particulates, response to different loading conditions, as well as to determine the influence of strain rates and temperature to develop high-performance nanocomposites. Further, HRTEM and electron diffraction studies are required to confirm the presence/absence of secondary in-situ reactions due to the presence of secondary phases and reinforcements in different types of processing methods. In addition, other kinds of nanometric reinforcements such as reduced graphene oxide (rGO) with different sizes and shapes can be incorporated into the Al-matrix to develop new Al-based nanocomposites. Aluminum/(ceramic + metal) hybrid nanocomposites with different combinations of ceramic + metal hybrid reinforcements can additionally be explored to simultaneously improve the strength and ductility properties.

Summary

The present article reviews the recent advancements in the microstructural and tensile response of the aluminum-based nanocomposites containing different types of nano ceramic reinforcements processed using various synthesis techniques. The following conclusions can be drawn from this work.

- Al-based nanocomposites have great potential due to their superior overall performance. These composites are foreseen to have considerable applications in weight-critical automobiles, sports, aerospace, electronics sectors.
- Literature review clearly validates that nanoparticles reinforced aluminum composites can be prepared using different routes such as powder metallurgy, squeeze casting, spark plasma sintering, etc. However, the powder metallurgy assisted microwave sintering route is one of the most promising routes in the context of cost, time and energy savings.
- Mechanical properties including hardness and tensile properties of the Al-based nanocomposites synthesized using powder metallurgy-microwave sintering-hot extrusion process are superior compared to other synthesis routes like casting, ultrasound-assisted stirring, and spark plasma sintering.

Nomenclature

Al	Aluminum	SEM	Scanning electron microscope
Al ₂ O ₃	Aluminum oxide	SGC	Stir gravity casting
AMMCs	Aluminum metal matrix composites	SiC	Silicon carbide
ARB	Accumulative roll bonding	Si ₃ N ₄	Silicon nitride
BN	Boron nitride	SiO ₂	Silicon dioxide
CNT	Carbon nanotube	SPS	Spark plasma sintering
CS	Centrifugal casting	TiB ₂	Titanium diboride
GPI	Gas pressure infiltration	TiC	Titanium carbide
HEBMMS	High energy ball milling and sintering	TiN	Titanium nitride
HPCI	High-pressure centrifugal infiltration	TiO ₂	Titanium dioxide
MI	Melt infiltration	Ti ₃ SiC ₂	Titanium silicon carbide
MMCs	Metal matrix composites	UCS	Ultimate compressive strength
MS	Microwave sintering	VGS	Vacuum gas sintering
MWCNT	Multi-wall carbon nanotube	VPI	Vacuum pressure infiltration
PI	Pressure infiltration	WS ₂	Tungsten disulfide
SC	Stir casting	ZnO	Zinc oxide
SD	Spray deposition	ZrB ₂	Zirconium diboride
SE	Screw extrusion	ZrO ₂	Zirconium dioxide

Glossary

Alloy A substance that has metallic properties comprising of two or more chemical compounds, at least one of which is a metal.

Casting A process whereby hot liquid metal flows into a mold and solidifies in the mold cavity shape.

Cavitation The formation of space within a solid object or body.

Cohesion The force with which like particles are bound together.

Composite A combination of two or more insoluble materials in each other, which exhibit superior properties to either of the component materials.

Corrosion resistance The ability of a material to resist damage due to oxidation or other chemical reactions caused by corrosion.

Crucible A ceramic pot made of reasonably high thermal conductivity materials such as graphite, bonded with clay or carbon, and used for melting metals.

Debonding It occurs when a reinforcement particle stops adhering to the substrate material (matrix).

Dendrite A crystal with branched appearances formed during the solidification of alloys.

Dispersion Distribution of secondary phase like reinforcement particles in a continuous phase like matrix material.

In-situ The reinforcement is formed within the matrix by reaction during the processing.

Metal matrix Acts as a continuous phase and accommodates the reinforcement material.

Nucleation The process that arises in the development of a crystal from a solution that arranges a small number of atoms, ions, or molecules in a pattern typical of a crystalline solid, creating a site where new particles are deposited as the crystal grows.

Reinforcement Material that enhances the strength or other mechanical properties of the composite.

Introduction

Wrought alloys of aluminum are usually linked to ductility, stiffness, higher strength, excellent resistance to corrosion, and excellent electrical conductivity (Stjohn and Nie, 2017). Cast alloys have appealing characteristics such as low melting point, high fluidity, stiffness, excellent corrosion resistance (Okayasu *et al.*, 2013), and superior as-solidified strength. Cast alloys are commonly used as castings of sand and die-castings. Casting alloys used in the most significant quantities contain silicon additions of 9.0%–13.0% far exceeding the amounts in most wrought alloys. Silicon is the alloying component, which makes the high-volume aluminum casting industry's business viability possible. Silicon content from 4.0% to 12.0% eutectic level reduces scrap losses, allows the manufacturing of much more complex models with higher section thickness differences, and yield castings with better

Fig. 1 Various matrix and reinforcement materials used for the production of MMCs. Reproduced from Arunachalam, R., Kumar, P., Muraliraja, R., 2019. A review on the production of metal matrix composites through stir casting – Furnace design, properties, challenges, and research opportunities. *J. Manuf. Process.* 42, 213–245.

performance. These advantages stem from the impacts of silicon in growing fluidity, decreasing cracking, and improving feeding to minimize porosity during shrinkage. Their high resistance to corrosion makes these alloys beneficial for marine, aerospace, and automotive construction (Okayasu *et al.*, 2013). These cast alloys are used in the production of metal matrix composites (MMC). MMCs are metals that are reinforced with other metals, ceramics, or organic compounds (Ramnath *et al.*, 2014). MMCs are produced by dispersing some weight or volume percentage of reinforcements in the matrix materials. Various metals are available as matrix materials for the production of MMCs; some are Al, Mg, Cu, Fe, and Ti. Aluminum and its alloys are commonly used in the production of MMCs, among others. Due to its excellent thermal, mechanical properties, high strength to weight ratio, and superior corrosion resistance, AMMCs are potential materials for various applications. In the automotive industry, AMMCs find many applications, such as pistons, cylinder liners, brake rotors, driveshafts, and others.

Fig. 1 displays the various matrix and reinforcement materials that can be used to produce MMCs. The numerous inorganic reinforcements such as oxides (aluminum oxide, titanium oxides, zirconium oxides), carbides (silicon carbide, titanium carbide), nitrides (titanium nitride), borides (titanium boride, zirconium boride) are commonly used but are fairly expensive. Organic reinforcements such as fly ash and red mud significantly improve the strength of the composite, and its cost is relatively low.

The reinforcements could be particulates, fibers, or laminates. The reinforced composite using particulates plays the leading role in the manufacture of AMMCs, as they are readily available, inexpensive, and easier to disperse in the matrix. Among the various micro to nanosize reinforcement particles, SiC, B₄C, Al₂O₃ are the most widely used reinforced particles. These reinforcement particles improve the hardness and elastic modulus but enhance the wear resistance (Huang *et al.*, 2019). Due to its high hardness, specific strength, stiffness, and thermal properties, SiC is added while Al₂O₃ exhibits strong compressive strength and wear resistance. Boron carbide is one of the toughest known elements and has high elastic modulus and toughness to fracture (Arunachalam *et al.*, 2019).

The primary production processes for the manufacturing of aluminum MMCs can be classified according to the state in which they are shaped: Liquid state and solid state processes (Nturanabo *et al.*, 2019). The liquid state processes are further classified into liquid metal infiltration and liquid metal casting processes, as illustrated in **Fig. 2**. Specifically, liquid metal casting processes are the primary route for producing MMCs. The infiltration of liquid metal from such matrix alloys into a wide range of ceramic, boron, and carbon reinforcements had been a popular route for the production of such MMCs (Lim and Clegg, 1997). The production processes have a substantial impact on both the mechanical properties and production costs. **Fig. 2** also shows other methods (semi-solid and others, including in situ) used in the production of MMCs.

Within the liquid processing route, stir-squeeze casting is more widely used due to its simplicity and versatility. The stir-squeeze cast is a combination of casting (like in hydraulic forging) and squeezing. In this method, the solid material is heated above its melting point. Then the liquid metal is stirred with a stirrer creating a vortex into which the reinforcement material is added. The vortex created helps to produce a homogeneous mixture, and then the mixture is poured into a preheated die and subsequently

Fig. 2 The various production process for MMCs. Reproduced from Arunachalam, R., Kumar, P., Muraliraja, R., 2019. A review on the production of metal matrix composites through stir casting – Furnace design, properties, challenges, and research opportunities. *J. Manuf. Process.* 42, 213–245.

hardened under the influence of a relatively high external pressure, using a hydraulic press. A hot runway pipe from the furnace to the die conveys the molten metal. The key advantages of this process are mass production flexibility, improved wettability between reinforcement and matrix material, and excellent mechanical properties due to the relatively high-pressure solidification (Panwar and Chauhan, 2018).

The suggested range of process parameters for stir-squeeze casting is given in Fig. 3. Among these parameters, squeeze pressure is the most influential. Most previous researchers stated 100 MPa squeeze pressure is ideal for grain refining and lower porosity. No substantial impacts were noted after 100 MPa squeeze pressure (Dhanashekar and Senthil Kumar, 2014). In order to enhance the product characteristics, squeeze stress holding time is recognized as the most influential factor. Therefore, the holding period between 30 and 45 s was suggested, after which there was no impact on the heat dissipation rate (Senthil and Amirthagadeswaran, 2012). The recommended melt temperature for aluminum alloys and composites is 700°C for the squeeze casting method. As the melt temperature decreased from 780 to 680°C, the microstructure gradually became finer, and the grains became smaller (Maleki et al., 2006). The temperature of the melt should be above 700°C for adequate infiltration of reinforcement (Yong and Clegg, 2005). Aluminum alloy tensile strength and elongation were reported to be rapidly enhanced as the preheating temperature of the die was increased from 200 to 250°C, but no drastic changes were observed with temperatures between 250 and 300°C. If the die temperature is further increased to 350°C, the tensile strength and elongation suddenly decreased, and many rosette particles were

Fig. 3 Recommended process parameters for stir-squeeze casting process. Reproduced from Arunachalam, R., Kumar, P., Muraliraja, R., 2019. A review on the production of metal matrix composites through stir casting – Furnace design, properties, challenges, and research opportunities. J. Manuf. Process. 42, 213–245.

also observed in the microstructure (Dao *et al.*, 2012). To achieve a homogeneous mixture, the duration of the stirring time should be higher than 5 min and less than 10 min. The agglomeration of particles is observed over 10 min of stirring, thus reducing the mechanical properties of the composites (Umunakwe, 2017). The gas formation, oxide skin, and porosity were observed at higher stirring speeds (700 rpm) due to turbulence. At lower speeds, it was not appropriate to mix reinforcement with matrix, while the reinforcement was isolated from the vortex (Prabu *et al.*, 2006). The stirring speed of 600 rpm produces homogeneous mixture and less porosity in the MMCs, resulting in improved mechanical properties of the composites produced. The percentage of reinforcement purely depends on the desired properties of the AMMCs; for SiC and Al₂O₃ micro-sized particles, it was found to be 10% and 5%, respectively. For most reinforcement particles, preheating temperature of 250–300°C is suggested.

The focus of this article is on the mechanical properties, the mainly compressive strength of AMMCs produced through various production processes but primarily through the casting process. Based on the recent and relevant available literature, the mechanical properties, current applications, and the general strengthening mechanisms are discussed in the forthcoming sections.

Mechanical Properties of AMMCs

In compression testing, the sample or the component is compressed between two moving platens. A load cell and an extensometer or strain gauge are used to measure load and displacement. Compression tests are useful for testing material or component load-bearing capabilities under compressive loads. Compression pressure, for example, is taken into account in the design of tower structures, columns, bridge structures, and other load-bearing structures (Touchstone, 2020). The test is quite simple to conduct as well as the preparation of samples for testing. According to ASTM E9-09 (Reapproved 2018), solid cylindrical specimens of varying dimensions (short, medium, and long) can be used based on the availability of the sample materials (ASTM, 2010).

Material compression testing can be divided into two forms depending on the speed of the test: Static and dynamic modes. Static testing requires rates below 1 mm min⁻¹, while dynamic testing takes place at speeds > 10 mm min⁻¹. Static testing can be further categorized into axial and plane strain compression testing. The axial compression tests can provide the yield strength, ultimate strength, and modulus of materials that are used in the design of equipment structures and others. The plane strain compression test can be used in assessing the flow stress properties of materials, which is essential in selecting/sizing the

equipment in the manufacturing process such as rolling, forging, and extrusion. Besides, tests like flatwise compression testing are used in evaluating the collapse properties of laminates and composites (Touchstone, 2020).

AMMCs are potential materials for a wide variety of applications, such as aerospace, transportation, and defense due to their lightweight and excellent mechanical properties. Some of these applications, especially in aerospace and defense, the structural components are subjected to dynamic loadings such as bird hit or missile attack during their service life (Jo *et al.*, 2019). Compression load conditions are encountered in structural sections such as fuselage/pressure cabin lower skin, upper wing skin stringers, and lower horizontal stabilizers of a typical aircraft (Gloria, 2019). Compressive yield strength is the leading engineering property required for these aircraft applications. Not much literature reports the compressive response of AMMCs, and among the available literature on compression strength, most of them focus on the static mode, especially the axial-load compression testing and very few on the dynamic conditions.

Stir cast AMMCs are manufactured by adding reinforcement particles of different sizes ranging from micro to nano into the molten Al metal matrix. Most of the ceramic reinforcements do not have the wettability to be uniformly mixed in the matrix, and namely, wetting agents like magnesium (about 1 wt%) is added. Even with that, the reinforcements are not uniformly distributed, and other factors such as stirring speed, stirring time, stirrer blade configuration, and amount of reinforcement added significantly influence the distribution. Heterogeneous distribution of reinforcement particles has a negative influence on the mechanical properties such as compressive strength of MMC (Aktaş and Anil, 2018). Tables 1 and 2 summarize the mechanical properties of different AMMCs developed by researchers worldwide over the last ten years using micro and nano-sized reinforcing particles, respectively, through the stir casting route. The compressive strength impact of Al_2O_3 content is substantial. Thicker Al_2O_3 interface can result in stress localization, resulting in reduced mechanical characteristics (Tahamtan *et al.*, 2013). Thus, the compression strength of nanocomposites is higher than that of micro-composites because, in strengthening the composites, nano-particles are more efficient (Sajjadi *et al.*, 2012). The addition of 8% TiC particulates enhances the mechanical behavior of AA 7075 composites (Rao *et al.*, 2014). By increasing the weight percentage of microsize SiC particles, the compressive strength increases. The improvement in compressive strength can be attributed to the grain refinement and intense multidirectional thermal stress at the Al/SiC interface, which plays a significant role. SiC particles have a grain-refined strengthening effect, which is improved by increasing the weight percentage of SiC particles. The SiC particles function as the heterogeneous nucleation catalyst for aluminum during solidification (Rana *et al.*, 2015).

It is observed from Tables 1 and 2 that the particle size plays a critical role in improving the composite strength. The hardness and compressive strength are higher, and the porosity percentage is lower for the composites produced with nanosize particles as reinforcement.

Kumar *et al.* (2019) examined the feasibility of using scrap aluminum alloy wheels (SAAWs) from cars as matrix material and spent alumina catalyst (SAC) from oil refineries as reinforcing material, and compared the properties with LM25 as matrix and pure Al_2O_3 as reinforcement. To determine the compression characteristics and fracture patterns, the compression test was performed on four distinct samples. Fig. 4 displays the stress-strain curves obtained from the compression test carried out on the LM25 + Al_2O_3 composite. The LM25 + Al_2O_3 composite showed the highest compressive strength at deformation up to 8 mm from the initial height. In contrast, the LM25 + spent alumina catalyst composite showed the lowest compression strength value with a significant decrease in the composite's load-bearing capacity. The impact of the reinforcement type and its size on both the tensile strength and the compressive strength was substantial. LM25 + Al_2O_3 reinforced composites display improvement of 48% in the ultimate compressive strength relative to those reinforced with spent aluminum catalysts. This result demonstrates a significant impact of alumina mixed with a silicon eutectic phase on reinforcing composites by serving as a barrier to the propagation of cracks. The presence of a friction constraint between the flat sample contact ends resulted in the compressed samples having a non-uniform plastic flow. Such non-uniformity of flow and associated materials weakened the composites and caused shear deformation in the diagonal plane. The higher concentration of Al_2O_3 compared to the spent aluminum catalyst and the higher Si content in the LM25 matrix compared to the scrap aluminum alloy contributed to the creation of more nucleation sites for the mixture of alumina and eutectic silicon. The increase in the number of nucleation sites helps to achieve smaller grain sizes because of which the ultimate compressive strength is substantially higher in the two composites. The combination of acicular eutectic silicon and grain boundary reinforcement improved the mechanical characteristics. The intergranular distribution at the grain boundary provided better mechanical properties and prevented failure along the grain boundary. The smaller grain size of the LM25 matrix and the addition of Al_2O_3 led to enhanced mechanical characteristics. The smaller size of the aluminum reinforcement provided the eutectic silicon phase with additional nucleation sites (Kumar *et al.*, 2019).

Table 3 lists the latest applications of various AMMCs. It is very clear from this table that AMMCs have commercial significance, and so researchers can make use of it to advance the utilization of AMMCs. Table 3 could serve as a swift reference in selecting an AMMC for the mechanical properties/applications required.

Strengthening Mechanisms in AMMCs

Most of the engineering materials (metals and alloys) used in engineering are load-bearing materials. Hence, these materials must have adequate strength so as not to fracture during loading and also retain their strength (Bhat and Arunachalam, 1980). Strengthening of material is necessary because metals and alloys usually do not exhibit the desired strength due to the nature of metallic bonding and also because of a number of defects in the lattice. It is not recommended to change the crystal structure of the material or to change the nature of metallic bonding as it may lead to a brittle material. Strengthening of material should be

considered towards strengthening the lattice structure against various flow processes such as plastic flow, strengths at high temperature, and high rates of deformation (Lavernia and Schoenung, 2017).

In MMCs, based on the features of the reinforcement particles, which are secondary phases, the strengthening mechanisms can also be classified into direct and indirect. Direct strengthening is a result of the load transfer from the matrix to the reinforcement. In contrast, indirect strengthening is attributed to the impact that reinforcements may have on the microstructure or deformation mode of the matrix (Gnjidic *et al.*, 2001). Many microstructural variables within this scheme can have an impact on strengthening. These factors include matrix alloy, aging conditions, particle volume fraction, and particle size. Strengthening in MMCs has been related to dislocations of a very high density in the matrix originating from differential thermal contraction, geometrical constraints, and plastic deformation during processing (Ibrahim *et al.*, 1991). Based on this, the strength exhibited by the engineering

or engineered materials is generally attributed to five different theories: Orowan, Hall–Petch, load transfer strengthening from the soft matrix to hard and tough reinforcement, Taylor strengthening (Huang *et al.*, 2019), and fracture strengthening. **Table 4** summarizes these different strengthening models.

The key mechanism in improving strength, especially with nano-scale reinforcement, is the Orowan strengthening. The reinforcement particles serve as an obstruction, preventing the dislocation movement, leading to a pile-up of dislocations. Such dislocations, bows, and bypasses the reinforcement by creating loops around them known as Orowan strength looping (Huang *et al.*, 2019). The Orowan strengthening mechanism is schematically illustrated in **Fig. 5**. Dislocations distort the crystal locally,

Table 4 Strengthening modes of AMMCs

S. No.	Strengthening models	Strengthening mechanism	Governing equation	References
1	Hall-Petch	Nanoparticles strengthen a material by pinning grain boundaries during thermomechanical processing resulting in smaller grain sizes which enhances the strength	$\Delta\sigma_{HP} = K_{HP} [D_f^{-1/2} - D_o^{-1/2}]$ where K_{HP} is the Hall-Petch slope, D_f is the average grain size of the composite and D_o the average grain size of as-cast alloy $\sigma_y = \sigma_0 + k_y d^{-1/2}$ where σ_y is the yield strength of the composite, σ_0 and k_y are the constants	Zhang <i>et al.</i> (2015) Huang <i>et al.</i> (2019)
2	Load bearing	Stiffer reinforcement phase will sustain higher local stress than the less rigid matrix	$\Delta\sigma_{LT} = \frac{1}{2} \sigma_{ym} V_f$ $\Delta\sigma_{LT} = \sigma_m [1/(2m)]$ where σ_m is yield stress of matrix and m is the volume fraction of reinforcement	Yang <i>et al.</i> (2017) Mirza and Chen (2015) Huang <i>et al.</i> (2019)
3	Orowan	Dispersion strengthening from the reinforcement particles	$\Delta\sigma_{Orowan} = \beta \frac{0.4 G_m b}{\pi \lambda} \left[\frac{\ln \left(\frac{d_p}{b} \right)}{(1 - \nu_m)^{1/2}} \right] \lambda = d_p \left[\sqrt{\frac{\pi}{4 V_f}} - 1 \right]$ $\Delta\sigma_{Orowan} = \frac{G b}{2\pi \sqrt{1 - \nu} [(0.779/\sqrt{f}) - 0.785] d} \ln \frac{0.785 d}{b}$ where G is shear modulus, b is burger vector, ν is the Poisson ratio, d is the grain size, f is the volume fraction of reinforcement.	Zhang and Chen (2006) Huang <i>et al.</i> (2019)
4	Taylor	The difference in coefficient of thermal expansion between matrix and reinforcement	$\Delta\sigma_{Taylor} = \sqrt{3} \varphi G_m b \left[\frac{12 V_f \Delta\alpha \Delta T}{b(1 - V_f) d_p} + \frac{8 V_{f,p}}{b d_f} \right]^{1/2}$ where b is burger vector of the matrix, φ is Taylor factor, ΔT is the difference in processing temperature and ambient temperature, d_p mean diameter of the reinforced particles, G_m is the shear modulus of the matrix, V_f is the volume fraction of the reinforced particles and $\Delta\alpha$ is thermal mismatch difference between matrix and reinforcement	Ibrahim <i>et al.</i> (1991), Chelliah <i>et al.</i> (2017)
5	Fracture strengthening	Fracture strengthening is to boost the fracture toughness of a material, which leads to an increase in strength. It is a combined effect of plastic dissipation and energy spent to start crack	$U_n = \frac{2G_f^1}{\sigma_f}$ where G_f^1 is the energy required to open the unit area of the crack. $2G_f^1 = \frac{K_{IC}^2}{E^j}$ where K_{IC} and E^j are the fracture toughness and effective Young's modulus of CNTs, respectively. The plastic deformation can be determined by using Johnson-Cook constitutive model equation $\bar{\sigma} = A + B \varepsilon^n$ where $\bar{\sigma}$ is the effective stress, ε is the plastic strain, A, B, and n are the yield strength, hardening modulus and coefficient of hardening respectively	Huang <i>et al.</i> (2019)

and the resulting energy is correlated with the local distortion. It gives the dislocation a line tension equal to the surface tension of a liquid. Stronger and more obstacles block the movement much more effectively because when substantial barriers are in its direction, the dislocation must bend between and around them, and thus the duration of the dislocation increases, as shown in Fig. 5. When the length of the dislocation line increases, the energy also increases, and this energy increases the stress required to distort the surface and strengthens the material. If the particles are far-off, the length of the line decreases with a decrease in strength. When both the size and the space of the dispersed particles are nano-dimensional, the change in strength is substantial (Ashby *et al.*, 2009).

Grain boundary strengthening is otherwise called a Hall–Petch strengthening model, which is a commonly accepted mechanism for the higher strength of AMMCs. According to the Hall–Petch effect, the strength is improved with the decrease in the grain size of the matrix (Huang *et al.*, 2019).

Load bearing is another process by which the reinforcement particles could reinforce a material. Fig. 6 shows a schematic illustration of the role of the various microstructures and interfaces in the potential load transfer for the vertical load applied (Yang *et al.*, 2017). The figure illustrates a simplified case of B_4C in an aluminum matrix, and the actual stress state could be quite complex in the actual material. In most microstructures, nano-reinforcement particles are mainly found at the grain boundary, triple point, and inside grain interiors. If nano-reinforcement particles are placed inside the grain, as shown in Fig. 6(a), the nano-reinforcement particles will stiffen the material. However, if nano-reinforcement particles are positioned at the grain boundary, the stress being transferred from Grain B will be transferred to Grain B' as shown by the dashed arrow. Fig. 6(b) illustrates the load-bearing mechanism of strengthening in the case of micro-reinforcement particles. If stress is transferred from Grain C, it must be

transferred to the micro-reinforcement particle because there is no adjacent matrix grain in the loading direction, as shown by the red arrow.

In Taylor strengthening mechanism, the volumetric strain occurs in the composite due to significant differences in coefficient of thermal expansion (CTE) between the matrix and the reinforced particles. To accommodate this CTE difference, dislocations are generated around the particles, thus increasing the flow stress in the matrix, which in turn increases the yield strength of the matrix (Gupta *et al.*, 2018).

Raj (2018) investigated the effect of reinforcing B_4C by conducting tensile testing on strengthening composites' behavior. The author has quantitatively analyzed the strengthening mechanisms and evaluated as a function of particle size and volume fraction. The yield strength of the composite rises considerably as the reinforcement particle was increased from 0 to 20 vol%. At a higher volume fraction of B_4C , the effect of thermal dislocation strengthening becomes more dominant as compared to other mechanisms (Raj, 2018).

The rapid cooling rate strengthens the alloy by preventing slipping. Srivatsan *et al.* (1995) implemented a quick cooling rate strategy. They obtained better high-temperature characteristics in aluminum alloys as a result of the growth of rapid solidification through the strengthening of the aluminum alloy matrix, which would fulfill the need for better high-temperature characteristics (Srivatsan *et al.*, 1995). Load bearing is not the only process by which the reinforcement particles can strengthen the material. When the reinforcement particles are tiny enough, they can reinforce the material by preventing the movement of the dislocation through the Orowan bowing. The grain boundary region can be improved by refining the components of aluminum alloy, which further increases the resistance to dislocation movement, enhancing the matrix yield strength. By using the Hall–Petch relationship, this increase in yield strength due to grain refinement can be calculated. Subsequently, thermomechanical processing of submicron-sized particles can contribute to the strengthening of Orowan in both coarse grain and ultra-fine grain regions (Zhang *et al.*, 2015). Matrix phase refining leads to the strengthening of the composites. During deformation, the grain boundaries effectively resist dislocation movement. The generation of dislocation density around the reinforcement particle due to difference in the coefficient of thermal expansion between matrix and reinforcement improves the hardness of the composites (Gupta *et al.*, 2018). Precipitates formed in the matrix also hamper dislocation motion. The dislocation on interaction with the precipitate is first bent due to the stress, then reconnected, and finally, the dislocation loops are formed around the particles. These dislocation loops hamper the motion of subsequently shaped dislocations and thus enhance the composite strength. In the micromechanics approach, the yield strength of the metal matrix can be calculated by considering the strengthening of grain refinement and Orowan strengthening.

Failure Modes of AMMCs

During the application of external loads, particle reinforced aluminum metal matrix composites exhibit different failure modes such as (1) the cracking of reinforcement particle (2) ductile failure by the void nucleation (3) interfacial debonding between the matrix and the reinforcement, and (5) matrix cavitation. An understanding of the mechanism of these failure modes is essential for improving the mechanical performance of metal–matrix composites for use in various engineering applications.

Particle Cracking

As per the fundamental theory of elasticity, the stress and strain patterns created at the initial loading point do not alter qualitatively during elastic loading but increase proportionally as the external load increases. On further loading, the plastic deformation in the matrix would lead to stress relaxation in the particles, which would delay the initiation of cracking in the material (Romanova *et al.*, 2009). The proportion between the bonding interface and the cracking of the particle relies on the form of the particle, the loading conditions, and the strength of the interface. In spherical solids, debonding dominates the cracking of the particles, while irregularly formed reinforcements display a scheme of cracking through the surface of the bulk. Debonding in compression manifests itself as individual patches, which are considered to be voids. These areas are sites of crack nucleation. When the cracks are further loaded, it spreads to the bulk of the particle (Romanova *et al.*, 2009).

Wu *et al.* (2016) synthesized and analyzed Al 7075/ B_4C composites with three different sizes of B_4C particles. The fracture mechanism is shown schematically in Fig. 7. Fig. 8 shows the SEM image of the fractured surface of the composite after compression testing. Micro-cracks were observed in the coarse B_4C powder. Pre-existing micro-cracks in B_4C particles continue to provide sites for crack nucleation and propagation. The rapid proliferation of micro-cracks leads to a surface fracturing with relatively low stress and limited macroscopic plastic deformation (Wu *et al.*, 2016).

For all particles, the first crack appears near the interface owing to the concentration of stress in adjacent boundary regions. Particle cracking at the interfaces increased with reinforcement content in the Al alloy (2014) matrix reinforced with Al_2O_3 (Srivatsan, 1996). Due to the intrinsic brittleness of the Al_2O_3 reinforcing particles combined with the tendency for it to fracture due to localized deformation results in particle cracking and particle–matrix interface debonding.

Gnjidic *et al.* (2001) researched the impact of SiC particles on the CW67 Al alloy and studied the compressive characteristics of the metal matrix composites produced by hot pressing. The research proved that the addition of SiC particles improved the yield strength and elastic modulus while reducing the ultimate compressive strength and ductility of the CW67 alloy in both peak-aged and under-aged circumstances. Adding larger size SiC particles contributes to cracking and adverse effects on the strengthening of

CW67 alloys. Compared to the under-age matrix, higher compressive strength and decreased ductility were obtained with the peak-age matrix. The presence of SiC particles caused the aging process to accelerate due to an increase in the dislocation density, which created more sites for precipitate nucleation (Gnjidic *et al.*, 2001).

The smaller particles had a higher impact on the strengthening of the matrix than the bigger particles. One possible reason may be that a damaged larger size particle generates a higher concentration of micro void than a damaged smaller particle. As a result, they would be anticipated to have significant surface defects. This observation is attributed to the enhanced probability that larger size SiC particles would be more probable to have a critical size defect causing a fracture at a specified stress point. In the event of larger particle sizes and larger interparticle spacing, the contribution of residual thermal stress is likely to be relatively insignificant, as is any reinforcement due to enhanced dislocation density. Therefore, a decrease in yield stress and elastic modulus can be anticipated. Besides, the fracture will continue to accumulate after yield, leading to rapid failure and reduced strength and ductility than would have been the case with a composite comprising smaller SiC particles. As a result, the percentage increase in strengthening achieved with a composite comprising larger size SiC particles is lower than that achieved with one containing

smaller size particles. The existence of SiC particles may be damaging to the ultimate compressive strength of the composite materials due to the addition of possible failure mechanisms such as unreinforced aluminum alloy cracking, particle–matrix debonding and particle agglomeration. The particle cracking has a significant impact on the ultimate compressive strength of SiC/Al composite products. Also, the likelihood of reinforcement cracking rises with an increase in particle size.

Void Nucleation

Voids are created by the debonding of the reinforcement from the matrix material (Kumar *et al.*, 2019). In all the composites that were produced and were reinforced with alumina as well as spent alumina catalyst, voids appeared due to debonding of the reinforcement particles from the matrix. The SEM Fig. 9 with the inset image shows a typical void created by the debonding of the reinforcement. The voids dimensions matched with the average reinforcement particle size of 50 and 150 mm for alumina and spent alumina catalysts, respectively. These voids are typically caused by the poor wetting of the reinforcement with the matrix, as well as weak interfacial bonding (Kumar *et al.*, 2019).

Lewandowski *et al.* (1989) studied the effects of matrix microstructure on the tensile fracture surface. They identified void nucleation below the tensile fracture surface of an over-aged SiC particulate reinforced AMMC (Lewandowski *et al.*, 1989). Sahoo and Koczak (1991)

investigated the effect of microstructure on the tensile fracture surface of TiC reinforced AMMC, which indicated ductile failure and sites for void nucleation (Sahoo and Koczak, 1991).

Interfacial Debonding

Matrix/reinforcement interfacial debonding is also one of the characteristic features of the fracture process. The schematic representation of bonded and debonded interfaces of reinforcement particles in the matrix is shown in Fig. 10.

Ozden *et al.* (2007) investigated the impact strength, microstructural, and fractographic analysis of SiC particle reinforced AMMC at different temperature conditions. The failure took place in the matrix or near the particle–matrix interface as debonding at between 200 and 300°C temperatures. When there is a failure of debonding in the particle–matrix interface, the impact strength of composites decreases significantly (Ozden *et al.*, 2007).

Rajan *et al.* (2007) investigated the microstructural and properties fly ash particle reinforced AMMC through different casting routes. They observed a significant reduction in tensile strength in fly ash composites, due to interfacial debonding. Fig. 11 shows the tensile fractography exhibiting a mixed-mode of fracture: Ductile fracture for the aluminum matrix and brittle fracture for the fly ash particle, and the inset figure shows clearly the partially debonded reinforcement particle (Rajan *et al.*, 2007).

Matrix Cavitation (Failure)

Cavitation in the matrix reduces the MMC's ductility as these cavities (voids) reduce the constraint on the plastic flow between the voids, thus encouraging flow localization and void coalescence. Voids usually nucleate when local tensile stress through an interface such as inside a particle, or when the matrix exceeds interfacial bond strength (interfacial decohesion), particle fracture stress (particle cracking), or matrix cavitation stress (matrix failure), respectively (Tham and Cheng, 2001). Whitehouse and Clyne (1993) observed cavitation development in the Al₂O₃ reinforced AMMC during tensile testing. The cavities are usually formed in the matrix adjoining the reinforcement, and approximately in line with the axis of the applied stress (Whitehouse and Clyne, 1993). Wu *et al.* (2019) developed a microstructure-based model to explain the material deformation and fracture of A359/SiC metal matrix composite. The fractured samples after the tensile tests were polished carefully, and Fig. 12(a)–(c) shows their typical microstructures. The light gray area is the matrix, and the dark gray zones are the reinforcement particles. In order to compare with the results of the microstructure-based model, an enlarged image that was obtained from the simulation is shown in Fig. 12(d). It can be seen that the particle fractures near its sharp corners because of stress and strain concentrations. The matrix surrounding the fracture particles fails around the crack tips, either by connecting the fractured particles or propagating along the tension direction (Wu *et al.*, 2019).

Conclusions

In this article, we have provided a comprehensive overview of AMMCs right from production to analysis of the strengthening mechanisms as well as failure modes of composite materials. Stir-squeeze casting is one of the most straightforward and established processes for the production of AMMCs through the liquid state processing route is discussed, and the recommended process parameters are proposed. With the advent of nanomaterials in the last decade, metal matrix nanocomposites with exceptional mechanical properties have been developed for promising applications in the automotive and aerospace sectors. The compressive strength of AMMCs is the main focus since hardly literature has focussed on this aspect of composites. AMMCs have been successfully produced through stir casting process with ultimate compressive strength ranging from 700 to 800 MPa even with relatively less than 5% weight percentage of nanosize reinforcement particles as compared to micro-sized reinforcement particles. The strengthening of AMMCs usually occurs through five different mechanisms: Orowan, Hall–Petch, load-bearing, Taylor, and fracture strengthening. Likewise, the composite materials can fail through any of these standard failure modes such as cracking of reinforcement particle, ductile failure by the void nucleation, interfacial debonding between the matrix and the reinforcement and matrix cavitation. Thus this article is expected to provide a far-reaching domain knowledge on the various aspects of AMMCs, especially concerning strengthening mechanisms and failure modes. The understanding of the strengthening mechanisms and the failure modes will significantly contribute to the production of quality AMMCs for high performance future industrial applications.

Fatigue Behavior of Magnesium Matrix Composites

Sravya Tekumalla, Nanyang Technological University, Singapore

Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introduction

In an ever-increasing quest for alternative environment-friendly materials for a sustainable planet, magnesium stands out due to its extremely low density and exceptional property profile such as high specific strength, excellent damping capacity, good machinability, etc. These properties render magnesium alloys useful in automobile applications, such as in low temperature exposure components like covers, engine cases, brackets, etc. (Ramalingam *et al.*, 2020). Demonstration of additional properties such as ignition resistance, low modulus, and electromagnetic shielding extend the applications of magnesium alloys to aerospace, biomedical and electronic sectors, respectively. In the last two decades, there have been numerous publications demonstrating the potential of magnesium composites as an attractive class of magnesium-based materials as they offer better thermal properties such as creep, strength, ignition resistance, electromagnetic shielding resistance, and corrosion. Magnesium matrix composites comprise of pure magnesium or a magnesium alloy as the matrix material with reinforcements such as ceramic/carbon based/amorphous/metallic materials varying in different length scales from micro- to nano-meter scales and hence termed as micro composites and nanocomposites. The effect of different reinforcements on the mechanical properties (i.e., strength and ductility) of magnesium is given in Fig. 1 (Gupta and Wong, 2015). In applications such as biomedicine, materials are subjected to repeated cycles of loading, wherein different human body parts are estimated to undergo different levels of cyclic stresses. For instance, during regular activities, human bones experience stresses up to 4 MPa while ligaments and tendons are subjected to peak stresses ranging from 40 to 80 MPa. Likewise, hip joints usually witness 3–10 times the weight of the body during activities like jumping. These stresses occur in the form of irregular repetitive cycles of loading and are estimated to reach up to 10^6 cycles/year. In order to serve as a potential replacement material/implant material, magnesium matrix composites need to withstand these conditions and demonstrate a good fatigue resistance. In materials science, the term “fatigue”, by definition, is the weakness in a material caused due to a repeated variation in stresses. According to the American Society of Testing and Materials (ASTM) (ASTM, 2013), fatigue is defined as “the process of progressive localized permanent structural change occurring in a material subjected to conditions that produce fluctuating stresses and strains at some point or points and that may culminate in cracks or complete fracture after a sufficient number of fluctuations”. Since failure by fatigue can occur despite the generated stress being lower than the yield point, it becomes imperative to study the conditions of fatigue crack growth to understand the fatigue lifecycle of the materials. Particularly, foreign reinforcements in otherwise homogenous magnesium matrix act as stress concentration and potential crack initiation sites promoting fatigue failure.

Depending on the origin of the stresses in materials, fatigue is classified into several types such as (1) Mechanical fatigue, (2) Thermal fatigue, and (3) Corrosion fatigue. Mechanical fatigue, the most commonly observed fatigue in metals, is a result of exposure to cyclic mechanical stresses for an extended period of time. Examples of fatigue failure include the 1954 De Havilland Comets airline crashes where the passenger jets had broken up in mid-air due to the presence of sharp corners in the window openings of the planes. These sharp corners acted as stress concentration sites that initiated cracks. Repeated stress cycles in the fuselage were generated from pressurization and depressurization of the aircraft during each flight which led to propagation of cracks over time. After a finite number of cycles, the crack reached a threshold/critical length that prompted fuselage shell failure. Thermal fatigue is a specific type of fatigue failure mechanism marked by the slow deterioration and subsequent cracking of a material subjected to alternate heating and cooling cycles during which the material's free thermal expansion/contraction is constrained partially or fully. Thermal fatigue may/may not occur with mechanical loads. The degree of damage is affected by the magnitude and frequency of the temperature swings. Historically, it is known to be one of the major reliability threats in structural applications (Bayani and Saebnoori, 2009). Corrosion fatigue is the degradation of a material subjected to simultaneous action of cyclic loading and corrosive environments. A routine feature of corrosion fatigue is the corrosion pits which lead to crack initiation and propagation in parts subjected to cyclic loads (van der Walde *et al.*, 2005), and therefore, corrosion pits that reach a critical size have detrimental effects on fatigue life of a component. Fig. 2(a) and (b) gives a typical example of corrosion fatigue failure.

While all the three phenomena do occur in magnesium matrix composites, this article broadly covers the mechanical fatigue of magnesium matrix composites unless stated otherwise. Despite the limited work done by the scientific community in the thermal and corrosion fatigue of composites, this article also highlights the potential research directions pertaining to those topics.

Mechanical Fatigue of Magnesium Matrix Composites

Mechanism of Deformation and Failure in Magnesium

With a hexagonal closed-packed (HCP) lattice structure and a c/a ratio of 1.624, magnesium does not obey the von Mises criterion to have five independent active slip systems for homogeneous deformation. Therefore, the ductility of the material is limited as it does not sustain a large amount of plastic deformation by slip. Instead, magnesium undergoes deformation by

Fig. 1 Schematic illustrating the role of particulate reinforcements on tensile properties of magnesium matrix. Image reproduced from Gupta, M., Wong, W.L.E., 2015. Magnesium-based nanocomposites: Lightweight materials of the future. *Materials Characterization* 105, 30–46.

both slip and twinning based mechanisms. Among various deformation modes (Albinmousa, 2020), the basal (0001) slip and the (10 $\bar{1}2$) tension twinning are the easy modes of activation owing to their low critical resolved shear stresses (CRSS). In cyclic loading, especially involving tension-compression cycles, apart from slip, a twinning-detwinning deformation mode is experienced by magnesium alloys and composites (particularly, wrought). This is because of a tension-compression asymmetry experienced by the materials which results in a stress asymmetry leading to a high mean stress. This article presents different aspects of fatigue of magnesium matrix composites, including the role of micron, sub-micron, and nano reinforcements on the fatigue life, followed by the microstructural aspects of the composites. For more information on the general concepts of fatigue including experimental methods, fatigue life equations and damage models, the readers are redirected to the article by Albinmousa (2020).

Fatigue of Magnesium Matrix Composites

Micron size reinforcements

Amorphous reinforcements

Amorphous alloys are a class of metallic materials that are not crystalline in nature as compared to most metals, but demonstrate great properties such as high strengths (in the order of 1–2 GPa), high elastic strain limits of up to 2%, good corrosion resistance, etc., (Inoue, 1995). Given the unique nature of amorphous alloys, researchers have used these amorphous materials as reinforcements for making lightweight metal matrix composites. Nafar Dastgerdi *et al.* (2016) reinforced micron sized amorphous alloy particles of composition Ni₆₀Nb₄₀ (by at%) via blending different fractions (3% and 5% by volume) of it with Mg powder, followed by compaction, sintering and extrusion. They conducted fatigue loading at $R = -1$, frequency = 20 Hz at room temperature and reported that the specimen with uniform distribution of particle possessed superior fatigue resistance and higher fatigue limit. Further, they demonstrate higher fatigue life of composites reinforced with amorphous particulates as compared to pure Mg in high cycle region as given in Fig. 3. As one would expect, the fatigue crack initiation occurred preferentially at particle-matrix interfaces with multiple cracks initiated at the interface between the Ni₆₀Nb₄₀ particles and the matrix. These small cracks tended to propagate without interacting with other cracks. However, with time, these multiple cracks coalesce with one another to propagate and grow. Therefore, the fatigue behavior of the composites with amorphous particulates is strongly interlinked with the particulate distribution in the microstructure which, of course is a derivative of the processing conditions. In non-uniformly

Fig. 2 (a) A F-18 aircraft wing trailing edge flap undergoing corrosion fatigue failure; (b) Micro-section of region that underwent fatigue cracking.

distributed microstructures, several cracks coalesce together, while microstructures with uniform particle distribution witness, fewer fatigue crack coalescence, therefore delaying the fatigue failure.

Fibers

Alumina fibers

Nunes *et al.* (1986) studied ZE41 magnesium matrix with different volume fractions of alumina fibers (35, 40, 45, 55 vol%) with $R = 0.1$ under controlled loads at room temperature. Since the alumina fibers are much stronger than the magnesium matrix, they can take far superior loads when the composite is loaded. Hence, the tensile and fatigue deformation of the ZE41A/FP composites is controlled by the fracture of the fibers, with the final fracture occurring when enough fibers were fractured and congregated at a particular region. The authors also note the change in the mechanical properties with a change in orientation of the fibers, however, at any given orientation, the composite always demonstrated superior mechanical properties as compared to the base alloy (up to 40% higher), which demonstrates the positive effects of reinforcement on the mechanical properties such as tensile and fatigue as given in Fig. 4 for ZE41 with 55% FP composite. Further, apart from the reinforcement, the authors also highlight

Fig. 3 (a) S–N curves of Mg/Ni₆₀Nb₄₀ amorphous particles reinforced composites; (b) Cracks initiation and propagation of Mg/5Ni₆₀Nb₄₀ composite.

the importance of matrix alloy chemistry on the final mechanical properties. A matrix with double zinc and five times zirconium content exhibited significantly higher tensile and fatigue properties.

In a similar study, Davidson *et al.* (1989) reported the retardation of the crack growth rates by the fibers in the composite. In materials having fibers oriented at 0° to the loading axis, the fracture of fibers ahead of the crack tip, followed by coalescence of the cracks with the main crack was the predominant mode of crack growth. When the fracture strength exceeded in the crack tip region, fracture of fibers was seen to occur, however no debonding of fibers from matrix was observed. However, when the orientation of the fibers was changed from 0° to 45° , cracks were noticed adjacent to interfaces and the fracture was mainly due to the interface debonding. Tevatia and Srivastava (2015) proposed an analytical model based on the modified shear lag (MSL) theory which better agrees with the fatigue crack growth life for both low cycle and high cycle fatigue applications. Although validated by experiments on aluminum based short fiber MMC under the total strain-controlled settings, the authors propose the validity of the model for all metal matrix composites which proposes: a higher amplitude of plastic strain amplitude, a higher fiber volume fraction, and a high cyclic strain hardening exponent and low cyclic strength coefficient lead to an increased fatigue crack growth life.

Carbon fibers

Carbon fibers were also studied as reinforcement to a AZ91 magnesium alloy matrix by. Qi *et al.* (2017) and focus was laid on understanding the fatigue behavior of the composites. Load-controlled tests were performed with the $R = 0.1$ at a frequency of 15 Hz, hence it must be noted that there was no introduction of compressive stresses. It was estimated that the fatigue limit of the Mg/Cf composites was 250–270 MPa i.e., about 65%–70% of their ultimate tensile strength (~ 385 MPa). These composites showed high fatigue resistance did not fail at loads where cycles exceeded 10^4 demonstrating a reinforced fatigue behavior. Like alumina

Fig. 4 Fatigue of ZE41/FP composite and ZE41A magnesium alloy at a test temperature of 24°C and a constant fiber volume fraction of 55%. Reproduced from Nunes, J., Chin, E.S., Slepetz, J.M., Tsangarakis, N., 1986. Tensile and fatigue behavior of alumina fiber reinforced magnesium composites. *Metallurgical Transactions A* 15, 1397–1405.

fibers, the carbon fibers also show “interface weakening effect” with the matrix due to the debonding of the fibers with the matrix which eventually results in pull-outs of fibers and numerous cracks as shown in Fig. 5. As the applied max. load/cycles increases, there is an increased fiber pull-out and cracks cycles leading to “interface weakening effect” which is detrimental to the fatigue behavior.

Spherical reinforcements

Micron size spherical reinforcements such as SiC particulates have been added to Mg-6Zn alloy to study the mechanical properties including cyclic fatigue behavior. Llorca (1994) studied the micro composite in T4 and T6 conditions and noted that hysteresis loops shape of the composite in T4 condition is symmetrical (Fig. 6(a)) with compressive stresses consistently lower than the tensile stresses by 50 MPa upon fatigue loading. This is due to the tension-compression yield asymmetry displayed by magnesium alloys owing to their crystal structure. However, the authors report that the magnesium based composites were not as sensitive to cyclic loading as compared to aluminum based composites. In fact, the naturally aged magnesium composite demonstrated cyclic hardening while the artificially aged T6 composite did not due to the presence of Mg-Zn phase. Hence, the influence of secondary phases, apart from reinforcements, is critical in dictating the fatigue life of the composite. In another work on the same materials, Srivatsan *et al.* (2005) studied the fatigue at room temperature and elevated temperature (150°C) (Fig. 6(c)). The authors observed agglomeration of particles in the microstructure owing to the size of the particles and presence of weak Van der waal’s forces that exist between the particulates. Crack initiation was favored at low stresses because of the presence of hard and brittle SiC particles in relatively ductile and soft magnesium alloy matrix. At 150°C, the addition of particles showed an increased fatigue resistance (based on normalizing the cyclic stress amplitude with yield strength). Overall, because of constraints due to the hard and brittle SiC particles in the matrix led to the formation of stress concentration sites locally at the interface of matrix and reinforcement promoting fatigue failure in the matrix. The mode of fracture is through the crack initiation and growth in the interfaces and coalescence of voids.

Fig. 5 Microfracture of fatigued Mg/Cf composite.

Sub-micron reinforcements

For biomedical applications, [Sabet *et al.* \(2018\)](#) developed Mg/2.5 wt% HA (Hydroxyapatite) and Mg/5 wt% HA bio-composites (average particle size ~ 600 nm). High cycle fatigue tests on these composites showed superior behavior of the composites over pure Mg ([Fig. 7](#)) with $> 10^7$ cycles life. Mg/2.5HA performed better as compared to Mg/5HA composite at all stress amplitudes because of the improved strength of the materials with the reinforcements. The authors propose that the reinforcements helped in redirecting the crack propagation leading to fatigue life enhancement. Further, the authors also propose the possibility of agglomeration of HA particles which led to crack initiation in the composites.

Nano-size reinforcements

Ex-situ added nanoparticles

Ex-situ synthesis refers to the synthesis of the nanocomposites externally without the involvement of any unanticipated/unprecedented chemical reactions. Several nanoparticles such as Al_2O_3 , CNTs have been added to AZ31 magnesium alloy to study the role of nanoparticles on fatigue behavior. Based on a fatigue study of AZ31 alloy + Al_2O_3 nano-reinforcement ([Srivatsan *et al.*, 2013](#)) at room temperature, the nanocomposite displayed a delayed crack initiation and propagation as compared to the monolithic AZ31 alloy, and therefore a higher endurance limit (at 10^6 cycles) as given in [Fig. 8\(a\)](#). Further, the overload region in the nanocomposite showed a high density of dimples apart from microscopic voids, while the AZ31 alloy displayed striations indicating varying modes of deformation in the alloy and the nanocomposite. At elevated temperatures of 100°C, [Jabbari *et al.* \(2020\)](#) demonstrated that the effect of reinforcing particles becomes more significant on the fatigue strength and life of the nanocomposite. The nanocomposites underwent higher cycles of loading as compared to the monolithic alloy at all amplitudes. Additionally, at 100°C the nanoparticles enhanced the fatigue strength by 87%, and by 50% at 200°C. The improvement was

Reproduced from Srivatsan, T.S., Godbole, C., Quick, T., Paramsothy, M., Gupta, M., 2013. Mechanical behavior of a magnesium alloy nanocomposite under conditions of static tension and dynamic fatigue. *Journal of Materials Engineering and Performance* 22 (2), 439–453. Srivatsan, T.S., Godbole, C., Paramsothy, M., Gupta, M., 2012a. Influence of nano-sized carbon nanotube reinforcements on tensile deformation, cyclic fatigue, and final fracture behavior of a magnesium alloy. *Journal of Materials Science* 47 (8), 3621–3638.

attributed to the improvement in the tensile strengths of the nanocomposites at higher temperatures, especially at 200°C, owing to the presence of thermally stable nanoparticles which led to a desirable high cycle fatigue behavior in the nanocomposites at higher temperatures. This led to a delayed crack initiation, propagation, and growth, thereby improving the fatigue performance. Moreover, the nano particles have also been deemed to deflect or hinder the fatigue crack growth paths by acting as obstacles to the cracks.

With addition of nanoparticle-sized CNT reinforcements (Srivatsan *et al.*, 2012a), the AZ31/1CNT (vol%) composite also had an endurance limit that is 40% higher than AZ31 alloy (at $R = 0.1$ and $R = -1$). Therefore, the AZ31/CNT nanocomposites are deemed favorable from a cyclic fatigue standpoint as shown in Fig. 8(b). An improvement by 200% was observed in the HCF life with addition of CNT nanoparticles as reinforcement to AZ31 matrix. Therefore, it is proposed that addition of nanoparticles is regarded as the best option to increase the fatigue resistance of the magnesium matrix among all other reinforcements.

Fig. 9 (a) True stress strain curves of pure Mg, Mg-1.8Y and Mg-1.8Y/1.53ZnO nanocomposite with tension compression asymmetry values, (b) S-N curve of the alloy and nanocomposite ($R = -1$). Image reproduced from Tekumalla, S., Bibhanshu, N., Shabadi, R., *et al.*, 2018. Evolution of texture and asymmetry and its impact on the fatigue behaviour of an in-situ magnesium nanocomposite. Materials Science and Engineering: A 727, 61–69.

In-situ formed nanoparticles

In-situ synthesis typically refers to the “synthesis due to a chemical reaction in the reaction mixture”. This may be done because the species is unstable, and cannot be isolated, or simply out of convenience. It is known that nanoparticles, owing to their large surface energies/Van der Waals force between each other, tend to agglomerate in molten metal. Previous works demonstrated the formation of micro-clusters by ceramic nanoparticles which consequently segregate after ultrasonic processing stops (Min *et al.*, 2008). Recently, it is shown that the in-situ formation of nanoparticles reduces the tendency for agglomeration and therefore, generates a microstructure with uniformly dispersed nanoparticles (Tekumalla *et al.*, 2017). The prime advantage with the in-situ nanocomposites/in-situ evolution of nanoparticles is the feasibility of uniformly distributed nanoparticles in the matrix contrary to ex-situ composites. This helps in arresting the premature failure of the material. Hence, understanding the role of microstructure and in-situ reactions on the final fatigue behavior is critical. Tekumalla *et al.* (2018) studied the role of in-situ reactions on microstructure and mechanical behavior and reported the role of microstructure on tension compression asymmetry which in turn affects the fatigue properties of the in-situ nanocomposite compared to the matrix alloy. As shown in Fig. 9, the fatigue behavior of the in-situ nanocomposite is seen to be much better in contrast to Mg-1.8Y alloy. Further, the authors also correlate the SN curve

Fig. 10 Maximum stress vs. fatigue life of the AZ31 + Al₂O₃ + Ni hybrid composite at (a) $R = 0.1$ and (b) $R = -1.0$.

slope with tension compression asymmetry of the alloy and nanocomposite and conclude that a high TCA is an indicative of a steeper SN curve.

Hybrid reinforcements

Another approach of using a hybrid mix of reinforcements is sought to achieve materials with properties that cannot be achieved with one type of reinforcement exclusively. With this outlook, nano length scale aluminum oxide (Al₂O₃) particles were added together with micron sized Ni particles as reinforcements to AZ31 to form AZ31/1.5Al₂O₃ + 1.5Ni (vol%). [Srivatsan et al. \(2012b\)](#) reported superior fatigue life and fatigue limit for the magnesium alloy reinforced with the dual-particles by 50%–100%. The maximum stress vs fatigue life at $R = 0.1$ and -1.0 for the alloy and dual particle reinforced composite are shown in [Fig. 10](#). This suggests the beneficial role of the particles in delaying the crack initiation and therefore improving the cyclic fatigue resistance of the matrix.

Based on the micro, nano and hybrid reinforcements, it can be affirmed that the reinforcements addition, particularly nano-sized particles, assists in improving the fatigue life of magnesium significantly.

Microstructural Influence on Mechanical Fatigue Behavior

As can be seen from the section “Mechanical Fatigue of Magnesium Matrix Composites”, it is evident that the reinforcements have a significant effect on the magnesium matrix to achieve improved fatigue life. However, it must be noted that this increased fatigue life is ultimately dependent on the microstructure change brought out in the material due to the addition of the reinforcements. The different factors that influence the fatigue strength and endurance limit are detailed below:

Fig. 11 Grain size changes in magnesium nanocomposites with the addition of reinforcements. Image reproduced from Gupta, M., Wong, W.L.E., 2015. Magnesium-based nanocomposites: Lightweight materials of the future. *Materials Characterization* 105, 30–46.

Defects

Mayencourt and Schaller (2002) demonstrated that the presence of defects such as impurities, interfacial reactions and dislocations are detrimental for the fatigue performance of the composites. In case of Mg-2Si/Al₂O₃ composites, poor damping capacity, relaxation of mechanical stresses by accumulation of damage, and poor fatigue resistance was observed due to the presence of impurities in the matrix, which were a result of interfacial reactions. On the other hand, Mg-2Si/C composite demonstrate excellent mechanical fatigue resistance and damping capacity owing to the lower number of defects. In magnesium-based materials, mechanical stress relaxation relates to dislocation pinning–depinning friction mechanism from point defects, very similar to thermal stress relaxation. When the dislocation is free to vibrate, this mechanism is predominant and therefore promotes crack propagation.

Grain Size

It is generally observed that the addition of reinforcement like HA, CNT, Al₂O₃, and other particles decreases the average grain sizes of the Mg matrix significantly. Fig. 11 gives a complete overview of general decrease in average grain size of micro- and nano-composites in contrast to pure Mg. The most proposed reasons for grain refinement are synergistic influence of pinning effect of the particles and dynamic recrystallization (DRX) made possible during the casting and secondary processing such as hot extrusion (Srivatsan *et al.*, 2013). Jabbari *et al.* (2020) reported a 58% reduction in the grain size of the AZ31B/1.5Al₂O₃ (vol%) composite in contrast to AZ31 monolithic alloy. Following the Hall petch relationship, decreased grain size leads to increased strengths of the material therefore promoting fatigue strength of the materials significantly. Further, reduction in the grain size is one of the only strengthening mechanisms that also contributes to improved ductility. This also helps in improving the endurance limit of the materials.

Texture

Magnesium, typically, exhibits a strong crystallographic texture which strongly influences its mechanical deformation behavior. Different reinforcements influence the crystallographic texture differently (Tekumalla *et al.*, 2019) with certain nano reinforcements like ZnO and Y₂O₃ to pure magnesium matrix weakening the texture. It has been reported that an in-situ Mg-1.8Y/1.53ZnO

nanocomposite exhibits a strong two component texture (basal and prismatic) which led to a high tension compression asymmetry (TCA) of 1.63 in comparison to the near symmetric TCA (~ 1.07) in monolithic Mg-1.8Y alloy. Under compressive loading, extension twinning is favored in strongly textured materials such as the nanocomposite as given in Fig. 12, whereas the twinning is suppressed by the weakly textured materials. The activation of twinning in the nanocomposite under compression resulted in the pronounced TCA as slip governed the tensile deformation and twinning governed the compressive deformation. However, the fatigue strength is far superior to the alloy because of the strengthening due to the addition of nano-reinforcements.

Reinforcement (Size, Distribution, Orientation, Stability)

The distribution, size, reactivity, and orientation of reinforcement are all highly localized factors that affect the crack initiation and growth in particle reinforced magnesium matrix, especially in the vicinity of the crack tip. For instance, crack growth rate through an agglomerated region is much higher than the growth rate through a region of well-distributed particles or through the matrix. From the above sections, it is also evident that the smaller the size of reinforcement (i.e., nano scale) the higher the fatigue life and fatigue strength.

Reaction between reinforcement and matrix occurs because of prevailing thermodynamic rules and in the case of fibers in ZE41A matrix, for example, there occurs a loss in fatigue strength of the composite (by 19%) (Page *et al.*, 1984). The interfacial reaction zone (0.25 μm in width) is given in Fig. 13 where the location of interfacial reaction acts as crack initiation site. Due to the reaction of the fibers, there is also an accompanied decrease in the strength of the overall fibers by 20%. Further, because of the

Fig. 14 SEM image of a secondary crack located in the matrix of an off-axis fatigue specimen of Mg/Al₂O₃ fiber composite. Note that the cracking avoids fiber/matrix interfaces during subcritical crack growth (crack path denoted by arrows). (b) SEM image of the failure obtained in the scanning Auger microprobe. Fiber fraction and orientation. *Metallurgical Transactions A* 15 (7), 1389.

formation of a layer initially formed during solidification followed by the reaction/fusion zone of the fibers and matrix, the zone consists of strains from differential contraction which results in the generation of dislocations.

It is also commonly proposed that the fatigue deformation of magnesium matrix composites is a function of the orientation of reinforcements, particularly, fibers. In one study, magnesium was reinforced with 20-micron average diameter Al₂O₃ fibers (35 vol % and 55 vol%) such that the fibers were laid out in a unidirectional fashion (Fig. 14). With the resultant material having extremely large grains (spanning through thickness), the microstructure was similar for both the composites. Increasing the angle between fiber axis and the stress axis resulted in a reduction in the fatigue resistance (Fig. 15(a)). Further, the material with higher fiber volume fraction demonstrated higher increase in the fatigue resistance for the axial samples. Further, the data presented in Fig. 15(b) also indicates that fatigue resistance scales roughly with the UTS (0.6%–0.95% UTS). Generally, it was observed that the fatigue failure happened with cracking occurring across the fibers at roughly 90 degrees to their axial direction. The authors attribute the failure to process defects such as (1) breaking and falling of individual fibers perpendicular to the stress axis during processing and (2) clumping of Al₂O₃ fibers such that their size is an order of magnitude larger than the grain diameter. These led to the delamination of the fibers from the magnesium matrix. However, these process defects did not play a significant role in the crack initiation during off-axis loading. Fatigue crack initiation and propagation during off-axis loading occurred primarily through magnesium matrix. Hence, matrices with better strengths obtained through modification of alloy chemistry are recommended for increasing the off-axis fatigue resistance of the composites.

Thermal Fatigue of Magnesium Matrix Composites

Since magnesium matrix has a mismatch in coefficient of thermal expansion/contraction with its various ceramic, carbon-based, other metallic reinforcements, large thermal stresses can be introduced in the magnesium composites with any change in the environmental temperature. This can potentially result in localized deformation (both elastic and plastic) at the matrix-reinforcement interface. This leads to dimensional instability of the structure resulting in degradation of mechanical properties, also termed as *thermal fatigue*. With increased dislocation density near the matrix-reinforcement interface, there is a chance that ageing and consequently, over-ageing of the matrix can be accelerated. Huang *et al.* (2006) worked on the thermal fatigue deformation of magnesium alloy composites (AE42 alloy with short Al₂O₃ fibers, transverse and longitudinal) as shown in Fig. 16. The authors suggest that the residual strains in the materials developed as a result of thermal cycles are dependent on the heat treatment, fiber composition and fiber orientation (in magnesium matrix). The residual strain is seen to increase with thermal cycles in longitudinal sample, while decrease in the transverse samples. Further, the samples with T6 treatment that underwent ageing, was seen to have the lowest residual strains. This is ascertained to be because of the increase in the yield strength of the matrix with ageing treatment. The authors note that the thermal stresses are released through plastic deformation of the magnesium matrix under thermal cycling. These thermal cycles result in the degradation of properties via phenomena like matrix overaging and recovery. Therefore, a thorough understanding of the thermal fatigue failure phenomenon is essential in design of magnesium matrix composites for use in such conditions.

Corrosion Fatigue (CF) of Magnesium Matrix Composites

Corrosion fatigue (CF) is another common phenomenon of failure occurring due to the concurrent activity of repeated mechanical loading and aggressive environments i.e. it is the interaction of localized corrosive activity with irreversible cyclic deformation (Birbilis and Hinton, 2011). Typically, it occurs in implant devices when subject to physiological environments; the body fluid has a pH level ranging from 1 to 9 depending on the tissues. (Harandi and Singh Raman, 2017). Magnesium based materials are increasingly being recommended as candidates for temporary implant devices vis-a-vis screws, stents, pins, and bone plates due to their ability to degrade in physiological environment without causing any detrimental or toxic effects and aid in the bone healing process. This biodegradability of magnesium also assists in elimination of secondary surgery for removal of the implant materials. Recently, magnesium matrix composites are increasingly being recommended for biomedical applications due to their low modulus of ~ 45 GPa, very close to the human cortical bone (2–30 GPa) and high specific strengths (Dutta *et al.*, 2020), demonstrating a promising mechanical compatibility with the bone, thereby eliminating stress shielding effects, a common phenomenon for traditional implants such as Co-Cr, Ti64 and stainless steel. While there is no reported literature to the authors' best knowledge on CF of Mg matrix composites, there is some information available on magnesium alloys which could serve as guiding beacon for future research on magnesium matrix composites. Magnesium-Aluminum-Zinc alloys such as AZ91 have shown a rather controlled degradation and increased bone mass around them as demonstrated by Witte *et al.* in guinea pig femora (Witte *et al.*, 2005) and rabbit model (Witte *et al.*, 2007) and no adverse toxicity because of Al present in the matrix. Jafari *et al.*

Fig. 16 Residual strain vs thermal cycles of AE42 alloy and its composite (a) in cast condition; and (b) after T4 and T6 treatments. Image reproduced from Huang, Y.D., Hort, N., Dieringa, H., Maier, P., Kainer, K.U., 2006. Investigations on thermal fatigue of aluminum- and magnesium-alloy based composites. *International Journal of Fatigue* 28 (10), 1399–1405.

(2015) investigated CF life of AZ91 alloy and found that the AZ91 alloy was susceptible to CF. While AZ91 alloy undergoes fatigue due to the cracks initiating at inclusions, its fatigue life is much higher in air than in physiological environments such as m-SBF where cracking is enhanced because of pitting and hydrogen embrittlement as shown in Fig. 17(a). Similar studies were also conducted on WE43 alloy which showed a CF limit of 110 MPa in air in contrast to a CF limit of only 40 MPa in SBF as given in Fig. 17(b) (Gu *et al.*, 2010).

While magnesium micro-composites may not demonstrate promise in resistance to CF, with recent advances in magnesium nanocomposites in enhancing mechanical fatigue behavior as discussed above, magnesium nanocomposites would be excellent candidates for temporary implant applications as they not only enhance the corrosion resistance of magnesium, but also its fatigue limit (Johanes *et al.*, 2019). Further, nanoparticles in the magnesium nanocomposites can also be engineered for targeted drug delivery which further enhances the functionality of these potential temporary implant materials. However, there is a dearth in understanding of CF of magnesium nanocomposites in the scientific community and it is imperative to understand the cracking/failure mechanisms of magnesium nanocomposites under physiological environments and cyclic loading conditions to prove the nanocomposites useful for biomedical applications and this would be an exciting direction of research for researchers working in this field and industries commercializing magnesium composites as potential biomaterials.

Summary

Magnesium is an extraordinary candidate for lightweight applications such as in the aerospace, automobile, biomedical and electronic sectors. Because most of the engineering and biomedical applications involve cyclic loading, fatigue life estimation of Mg materials, particularly, composites is extremely critical for the efficient design and implementation of these materials. Under cyclic loads, the crack initiation in Mg materials is related to basal slip and the crack growth follows an intergranular or transgranular mechanism. In general, the crack propagation is faster in the case of Mg composites which can be strongly attributed to the microstructural constituents such as reinforcements. This article presents different aspects of fatigue of magnesium matrix composites, including the role of micron, sub-micron, and nano reinforcements on the fatigue life, followed by the microstructural aspects of the composites. Overall, a significant amount of works on the stress-life (s-N) highlight the role of reinforcements on the fatigue behavior of Mg. For example, the micro reinforcements such as fibers oriented 0° to the loading axis retard the fatigue crack growth while the those oriented 45° to the loading axis accelerate the crack propagation. Tremendous improvements in fatigue strength were also common in the case of nanocomposites that exhibit better interfacial integrity with Mg matrix. Overall, it is essential to note that the reinforcement addition must be incorporated using efficient processing methods that can produce a sound, defect-free microstructure without agglomeration of particles to achieve the best fatigue performance.

Introduction

Metal is one of the significant engineering materials known to man, which has been and is still being used in various technological applications. Interestingly, due to the advancement in scientific knowledge and technical know-how, there is a desire for new materials that could fulfill the specific requirements for different engineering applications, which could not be solely obtained from the metallic material. This led to the combination of metal/metal alloy with ceramic materials forming what is called metal matrix composites.

Metal matrix composites (MMCs) are advanced engineering materials consisting of metal (e.g., Al, Cu, Mg, Ti) as the matrix and the second reinforcing/strengthening phase (e.g., Al_2O_3 , Cr_2O_3 , SiC, TiC, B_4C , Cr_3C_2 , BN, Si_3N_4 , carbon nanotubes, etc.) to produce properties different from the parent or constituent materials. The reinforcing phase enhances the needed strength and stiffness properties of the composites, and this strengthening phase could be in the form of short/discontinuous fibers/whiskers or continuous fibers or particulates. **Fig. 1** illustrates the different categories of metal matrix composites based on the geometric forms (shape and dimensions) of the strengthening phase.

In general, the reinforcement of composite materials serves different purposes based on the specific needs for their desired applications. In many instances, all the expected material properties for a particular application may not be found in a single monolithic material; hence, the need to combine two or more materials to achieve these desired properties. Some of these properties ([Kainer, 2006](#); [Chung, 2010](#); [Macke et al., 2012](#)) for which composites are made are highlighted below:

- Improved yield and tensile strengths at ambient and elevated temperatures.
- Increased stiffness at room and high temperatures.
- Enhanced chemical and corrosion resistance.
- Increased thermal insulation or conductivity.
- Improved thermal shock stability.
- Increased electrical insulation or conductivity.
- Improved fatigue resistance, especially at higher temperatures.
- Enhanced abrasion and wear resistance.

Fig. 1 Categories of metal matrix composites based on the reinforcement forms.

Fig. 2 Effect of temperature on the strength of titanium alloys and titanium matrix composites. Reproduced from Hayat, M.D., *et al.*, 2019. Titanium metal matrix composites: An overview. Composites Part A: Applied Science and Manufacturing 121, pp. 418–438. doi:[10.1016/j.compositesa.2019.04.005](https://doi.org/10.1016/j.compositesa.2019.04.005).

- Controlled thermal expansion coefficient.
- Reduced material weight (low density).
- Improved fracture toughness and damage tolerance.
- Improved creep resistance.
- Enhanced energy absorption and vibration damping capabilities.
- Improved electromagnetic shielding effectiveness.

Interestingly, due to the possibility that the properties of composite materials can be engineered to fit the desired engineering application, composites have been employed in the design and manufacturing of diverse engineering components in various technological sectors. For example, composite materials have been used in marine, automotive, aerospace, energy, biomedical, electronics, cutting tools, construction, and defense industries. However, in this section, more attention shall be focused on the high-temperature properties of MMC materials and their subsequent applications in engineering design and components manufacturing.

High-Temperature Properties of MMCs

High-temperature properties of engineering materials are a vital concern in many applications such as power generation, aerospace, and automotive. This is because temperature plays a crucial role in determining the functionality and applicability of materials in specific technological applications. Fig. 2 depicts the influence of temperature on the ultimate tensile strength of titanium alloys and their composites. It is noticeable that the strength of these materials decreases with increasing temperature. However, it is noteworthy that the addition of SiC reinforcing particles to the titanium alloys enhances their temperature retention capacity. This behavior indicates that MMC materials have high thermal stability compared to their respective matrix alloys. For instance, some aluminum alloys cannot be used for a component serving at temperatures above 200°C since an increase in temperature beyond this affects their microstructure and mechanical properties significantly. Exposure to elevated temperature decreases the mechanical integrity as well as the oxidation resistance of most metallic alloys. Through a proper combination of the right ceramic reinforcement with the suitable matrix, the high-temperature properties of the resulting MMC can be improved.

High-Temperature Applications of MMCs

The choice of using metal-matrix composites for several high-temperature applications is dictated by their attributes, which can be tailored to suit the desired component design. Some of these attributes include high specific strength, high specific modulus, high-temperature strength retention, excellent creep, fatigue, and wear resistance. Due to the possibility to withstand high temperatures, MMC materials are used in resistors and other electronic components.

In the automotive industry, elevated-temperature applications are primarily concerned with the engines, transmission, and braking components (Nturanabo *et al.*, 2013). These components could experience temperatures higher than 300°C during service, which could substantially reduce the mechanical reliability of the components. For example, the automotive brake disks are

usually exposed to extreme temperatures as high as 700°C during braking. This severe temperature may lead to buckling, thermoelastic instability, thermal cracks, premature wear, brake fade, brake squeal and judder, bearing failure, phase transformation (especially in cast iron), or fatigue cracks on a disc surface (Thomas *et al.*, 2019). Aluminum and magnesium alloys have been prominent in automobile applications in recent times due to their lightweight characteristic. Unfortunately, it is somehow challenging to apply most of these lightweight alloys (e.g., Al and Mg alloys) directly for components, such as engine blocks, powertrains, and braking systems, serving in the severe working environment due to their relatively low strength and modulus, and poor wear properties at elevated temperatures (Shin *et al.*, 2019). By reinforcing these low-density alloys with ceramic materials, their specific strength, high-temperature strength, thermal stability, as well as their creep, fatigue, and wear resistance, can be improved, therefore, qualifying them as potential materials for replacing cast iron and other materials in engine and brake applications. Below are the major components that have been produced from MMC materials, especially aluminum matrix composite, for automobile applications.

The automobile brake disc or drum is a crucial component of the brake system, which is attached to the wheels of a car. When brakes are applied to a moving vehicle, a significant amount of power is generated in the form of kinetic energy. This kinetic energy is subsequently converted into thermal energy through the friction losses between the brake disc/drum and the pads. The brake disks are subsequently subjected to a high level of thermal load, which results in a sudden increase in the temperature of the system as high as 700°C (Thomas *et al.*, 2019). These brake components are predominantly manufactured from gray cast iron due to its good castability and machinability, high thermal conductivity and specific heat capacity, high scuffing resistance, high melting point, and high friction factor and strength, and lower cost (Rashid, 2014). The major disadvantage of the conventional brake disc material is its weight, which significantly impacts on the vehicle's fuel consumption and its low wear resistance that generates non-exhaust particle emissions, which are of most significant concern in recent times. This challenge has led many automakers to seek for alternative brake disc materials. Silicon carbide particles reinforced aluminum alloys (Al-MMCs) have attracted more attention for this purpose due to their tailorable attributes, including high specific strength and stiffness, excellent wear and friction performance, high thermal conductivity and creep resistance, high energy absorption and damping capacity, good oxidation, and corrosion resistance, and low thermal expansion (Stojanović and Ivanović, 2015; Thomas *et al.*, 2019). Fig. 3 shows a typical automobile MMC brake disc and drum that had been installed on different car models. For instance, MMC brake disks had been used in various vehicle models, including the Lotus Elise, Chrysler Prowler, General Motors EV1, Volkswagen Lupo 3L, Volvo V40 and the Toyota RAV4-EV (Macke *et al.*, 2012).

However, the primary concern for not fully adopting Al-MMC brake disks by the various automakers is their temperature withstanding capacity, which has been recognized as a design issue (Allison and Cole, 1993). Good thermal conductivity and high specific heat are the desirable properties of Al-MMC materials that make them suitable alternative automotive brake disc materials.

Fig. 3 A typical MMC brake drum (a) and disc (b), and installed MMC brake disc.

Fig. 4 Temperature distribution in (A) ventilated gray cast-iron (GCI) and (B) solid Al-MMC brake disks during a single stop from 190 to 0 km/h, and (C) during Alpine descent at a constant speed of 20 km/h over 20 min period. Reproduced from Thomas, A., Zervos, N., Eklund, A., Awe, S.A., 2019. Simulation study on the thermomechanical behavior of Al-MMC automotive brake disks. In: Eurobrake 2019. Dresden: FISITA, pp. 1–12.

Fig. 5 Typical pistons (a), engine block with cylinder barrel (b), connecting rods (c), and pushrods (d) made of Al-MMCs. Reproduced from Stojanović, B., Ivanović, L., 2015. Primjena aluminijevskih hibridnih kompozita u automobilske industriji. Tehnicki Vjesnik 22 (1), pp. 247–251. doi:10.17559/TV-20130905094303.

This implies that by carefully harnessing the Al-MMC properties when designing brake disc, the heat generated during braking can both be absorbed and dissipated more quickly, and consequently prevent temperature accumulation. The results of the recent simulation study reveal that the Al-MMC disc can perform comparably to the standard brake disks (Thomas *et al.*, 2019). Fig. 4(A) and (B) showed the temperature distribution in both the regular and Al-MMC brake disks when they were subjected to an abrupt stop from 190 km/h. The maximum temperature in the Al-MMC disc is approximately 8% lower than that of the conventional disc. The simulation results also depict that the maximum temperatures experienced by both GCI and Al-MMC disks after a downhill drive (Alpine descents) at a constant speed of 20 km/h for 60 min are 315 and 260 °C, respectively. This indicates that Al-MMC disc experienced about 17% lower temperature than the GCI disc, which is attributed to the excellent thermal conductivity and adequate geometry design of the Al-MMC disc.

Besides the brake disks, the other automotive components that have been produced from Al-MMCs are the pistons, connecting rods, engine cylinders, and pushrods, as shown in Fig. 5. These components serve under harsh conditions where the thermal

conductivity, thermal stability, low weight, and thermal expansion, excellent resistance to oxidation and wear, and high-temperature strength retention of Al-MMCs become beneficial. Engine pistons made of Al-MMC have been manufactured and used in Toyota diesel engine cars, and they are also commonly used in Asia and West Europe car producers. Also, the engines with cylinder barrel produced from Al-MMC material had been installed on Honda S2000 – sports cars, Acura NSX cars type, Porsche Bower motors, and Toyota Celica 2000 cars (Stojanović and Ivanović, 2015).

In the aerospace industry, MMC materials are used because of their high stiffness (Young's modulus), high specific strength, low coefficient of thermal expansion, enhanced strength retention at high temperature coupled with high thermal conductivity. The materials suitable for aerospace applications should be lightweight and possess the capacity to withstand elevated temperatures for a prolonged time in aggressive environments. However, by incorporating a suitable high-temperature ceramic fibers into an appropriate metal matrix, potential lightweight MMCs with the right high-temperature properties can be made. However, further research investigations are still required in this regard.

Most materials, especially the superalloys that are used in aircraft and power generation turbine components, are usually subjected to an extremely oxidizing working environment and elevated temperatures for reasonable periods. As a result of these severe serving conditions, the mechanical integrity of these materials is sometimes affected. Furthermore, the wear resistance of these superalloys at elevated temperatures is relatively low, leading to an increase in maintenance operations (Verdi *et al.*, 2017). MMC coatings with Ni-based superalloys matrices are developed to avoid such compromise and applied to enhance the mechanical integrity of the components. This MMC coating has considerably improved the maintenance situation of such components.

High-Temperature Mechanical Properties

The stress-strain curve provides the basic mechanical properties of MMCs. These properties include stiffness (young's modulus), yield strength, ultimate tensile strength and ductility. During high temperature operation of MMCs, dislocations strongly influence these strength properties and others like fatigue resistance and creep resistance thus affecting the performance of these composites. Generally, the young's modulus, yield strength and ultimate tensile strength of MMCs decrease with increasing temperature. Young's modulus and ultimate tensile strength of $\text{Al}_2\text{O}_3/\text{A6061}$ MMCs measured at room temperature, 170 and 220°C was observed to decrease with increasing temperature (Tanaka *et al.*, 1996). This was also observed by Garcia-Leiva *et al.* (2003) with $\text{Ti64}/\text{SiC}$ MMCs with tests performed at room temperature, 55 and 600°C. Lakshmikantha and Auradi (2020) studied $\text{Al}/\text{B}_4\text{C}$ particulate MMCs at 100 and 200°C, the ultimate tensile strength of the composites decreased with increasing temperature. Oñoro *et al.* (2009) reinforced A6061 and A7015 aluminum alloys with B_4C particles and tested their ultimate tensile strength at room temperature and elevated temperatures ranging from 200 to 500°C. The ultimate tensile strength was also observed to decrease gradually up to 200°C before an abrupt decrease. Liu *et al.* (2019) investigated the ultimate tensile strength of CNT's/Cu MMCs in the temperature range of 25–655°C and similar observations were made as with the other authors.

The decrease in young's modulus and ultimate tensile strength of MMCs with increasing temperature is mainly attributed to the softening of the metal matrix at elevated temperatures. Generally, the decrease is gradual in the temperature range of 25–200°C. As the temperature increases in this range, the mobility of dislocations increases causing them to slip thereby reducing the work hardenability of the MMCs. Once temperatures go beyond 200°C, dynamic recovery occurs in which dislocations begin to move, annihilate and rearrange into more stable configurations with relaxed interactions with neighboring dislocations thus causing a decrease in the strength of MMCs. Due to the increased plasticity due to dislocation motion at high temperatures, the ductility of MMCs generally increases with increasing temperature as shown by Oñoro *et al.* (2009). Other several factors that may result in a reduction in young's modulus, yield strength and ultimate tensile strength of MMCs with increasing temperature include the brittle fracturing of the reinforcing material and/or debonding at the interface between the matrix and the reinforcement. This may be caused by a mismatch in the thermal expansion coefficients of the matrix metal and the reinforcement. As the temperature increases, the expansion of the matrix metal is restricted by the reinforcement thus leading to the generation of thermal residual stresses at the matrix/reinforcement interface consequently affecting load transfer from the matrix to the reinforcement during high temperature operation. These residual stresses deteriorate the matrix/reinforcement interface and are often relieved through elastic relaxation and plastic deformation.

Materials subjected to static and elastic loads for a long period of time plastically deform in a process known as creep. At room temperature creep is negligible for most materials and only becomes significant at high service temperatures. Creep occurs in metals when they are required to operate at temperatures above 30%–40% of their absolute melting point. Creep curves (plots of increasing strain against time) provide an important property called the steady-state creep rate used to describe the creep behavior of materials subjected to certain loads at given temperatures. Generally, creep curves of materials can be divided into three distinct regions namely primary creep in which the creep rate decreases with increasing time due to strain hardening, secondary creep where the creep rate is nearly constant (steady-state creep rate) due to competing contributions from strain hardening and plastic deformation and lastly tertiary creep in which materials begin to neck and cavitate thus increasing the creep rate.

The dependence of the creep rate on the applied stress and temperature for metals and alloys can be described by the Norton equation given by;

$$\dot{\epsilon}_s = \frac{ADGb}{kT} \cdot \left(\frac{\sigma}{G}\right)^n \quad (1)$$

where A and n (the stress exponent) are material dependent creep constants, G is the shear modulus, b the Burgers vector, k the Boltzmann constant, T is the absolute temperature and σ the applied stress (Viswanath, *et al.*, 2015). The diffusion coefficient D is given by

$$D = D_0 \cdot e^{\left(\frac{-Q_C}{RT}\right)} \quad (2)$$

where D_0 is the frequency factor and Q_C the creep activation energy (Viswanath *et al.*, 2015). The stress exponent, n may take values ranging from 3, 5, 7 and 8 which provides information on the mechanism controlling the creep rate. A value of $n = 3$ indicates creep governed by the viscous glide of dislocations (Mohamed and Langdon, 1974), $n = 5$ and $n = 7$ represents creep controlled by dislocation climb at high and low temperatures, respectively (Sherby and Burke, 1968; Robinson and Sherby, 1969), and $n = 8$ shows creep controlled by lattice diffusion (Sherby, *et al.*, 1977). However, it should be noted that MMCs show no secondary creep region (steady-state creep) but rather a sudden transition from primary to tertiary creep resulting in a minimum creep rate. Therefore using Eq. (1) to calculate the creep rate of MMCs results in much higher values of the stress exponent than those observed with creep of pure metals and simple alloys (Evans and Knowles, 1980; Clauer and Hansen, 1984). The stress term in Eq. (1) is however often modified to an effective value to give stress exponents in the range of those of metals and alloys (Viswanath *et al.*, 2015).

The high temperature creep behavior of stir cast AZ91-SiCp composites investigated at 175°C under different stresses revealed a stress exponent ranging from 5.4 to 5.8 indicating that creep in composites was mainly attributed to high temperature dislocation climbing (Viswanath *et al.*, 2015). The same creep mechanism was also reported in SiCw/Al-Fe-V-Si composites tested at temperatures ranging from 300 to 450°C (Peng and Zhu, 2003).

In MMCs, ceramic reinforcements are characterized by extremely high resistance to creep, therefore the creep rate of MMCs at elevated temperatures is mostly governed by the movement of dislocations in the matrix. Dislocation movement in the matrix during creep occurs through dislocation slip or dislocation climb. The former occurs at all temperatures above absolute zero whilst the latter only occurs at high temperatures. Ceramic reinforcements in MMCs are able to restrict plastic flow in the matrix under elastic loads at room temperature, however, upon raising the temperature to creep conditions, atoms in the matrix gain enough mobility to cause dislocations to climb over the reinforcing fibers thus facilitating plastic deformation and hence increasing the creep rate. Moreover, new slip systems are generated at elevated temperatures further increasing dislocation movement and consequently the creep rate. The creep rate of MMCs can also be increased by the relative sliding of grains in the matrix due to plastic flow at the grain boundaries. This deformation process known as grain boundary sliding increases with temperature thus resulting in increased creep rates.

Fatigue resistance is one of the most crucial property for MMCs with applications in the aerospace and the automotive industry. Fatigue is associated with mechanical failure due to formation and growth of cracks in materials subjected to cyclic loads. Failure through fatigue usually occurs after a number of load cycles and strongly depends on service environments like temperature. The fatigue strength of MMCs generally decrease with increasing temperature. This was confirmed through investigations by Ochi *et al.* (2004) on the fatigue properties of $Al_2O_3/A6061$ MMCs at room temperature and elevated temperatures of 200, 350, 400 and 450°C. Fatigue failure of MMCs is characterized by localized plastic deformation in the matrix usually at creep temperatures. This causes the initiation of cracks at grain boundaries which may coalesce upon repeated loading thus ultimately leading to fracture. Moreover, the matrix/reinforcement interface is often a crack initiation site in MMCs due to the accumulation of thermal residual stresses and increased dislocation density at high temperature operation.

High-Temperature Corrosion Properties

High Temperature Oxidation

When exposed to high service temperatures, materials usually experience a degradation in their properties which is caused by chemical interaction between the material and the surrounding environment. Depending on the nature of the environment in which the material is exposed to, the metal can experience, hot corrosion, oxidation and sulfidation. Oxidation takes place when a metal reacts with atmospheric oxygen at elevated temperature. This chemical reaction results in formation of an oxide layer on the metal which may provide protection against further reaction of the metal and the environment that is only if the oxide layer is non-porous and adherent to the metal.

Oxidation of Pure Metals

When oxidized at high temperatures, a pure metal can form a single or multiple oxides and to show which oxide is formed at a particular temperature and partial pressure of oxygen the Ellingham diagram is used as a guide. The Ellingham diagram uses the thermodynamic principles to predict whether the pure metal can be oxidized or not at a particular temperature or and oxygen partial pressure. Taking Magnesium for instance, at very high temperatures magnesium oxidizes to form a single oxide of MgO as shown on the Ellingham diagram.

Fig. 6 The Ellingham diagram. Reproduced from Khanna, A.S., 2018. Chapter 6 – High-temperature oxidation. In: Kutz, M. (Ed.), Handbook of Environmental Degradation of Materials, third ed. William Andrew Publishing, pp. 117–132. doi:10.1016/B978-0-323-52472-8.00006-X.

Oxidation of Alloys

Unlike pure metals which have their oxidation relatively simple, oxidation of alloys is a bit complex as several oxides can form as the metallic elements constituting the alloy form their respective oxides based on the temperature and the partial pressure of oxygen. Although several oxides are shown to form as per the Ellingham diagram shown in Fig. 6, only the most stable ones will be retained whereas the less stable one vanishes with time. Also, this is not a straightforward process as there are a number of factors which include the concentration of alloying elements, stability of oxides of the constituting elements and their diffusion constants which determine the oxide layer to be formed.

Oxidation Kinetics

Oxidation kinetics is the variation of the oxidation rate with time. This is an important concept as it allows an engineer to be able to predict the life time of a component serving in high temperatures. The variation of the oxidation rate with time can be, logarithmic, parabolic or linear. From the three variations the parabolic variation shown in Fig. 7 is the most important and it states that the oxide layer formation is inversely proportional related to time, that is as the time increases the rate at which the

Fig. 7 Parabolic Kinetic behavior. Reproduced from Khanna, A.S., 2018. Chapter 6 – High-temperature oxidation. In: Kutz, M. (Ed.), Handbook of Environmental Degradation of Materials, third ed. William Andrew Publishing, pp. 117–132. doi:[10.1016/B978-0-323-52472-8.00006-X](https://doi.org/10.1016/B978-0-323-52472-8.00006-X).

oxide layer forms decreases continually. The bases of this law is that the oxidation process is governed by diffusion of either the metal ions diffusing from the metal towards the interface of the metal and oxide layer to react with oxygen and as the oxide layer that results from this reaction forms and grows slowly. The reacting metal ions and oxygen atoms take a longer time to diffuse through the oxide layer to the metal/oxygen interface where the reaction happens. This behavior is followed by most high temperature metals and alloys. As a result, components fabricated using such materials tend to have longer service life in high temperature environments.

It is very important to select the right material for fabrication of different industrial components for high temperature applications. The selection requirements for high temperature materials are:

- (1) Microstructural stability.
- (2) High melting point.
- (3) Maintain mechanical properties such as ultimate tensile strength, creep and fatigue strength.
- (4) Low corrosion rate.

Metals used for the fabrication of components for high temperature applications require great microstructural stability at high temperature so as to ensure that the material properties do not change as a result of change in the microstructure. In addition, one important aspect is high melting temperature of the metal, this ensures that the metal can be used for high temperature applications and it is also important that at those high temperatures, the metal should still maintain its tensile strength, fatigue strength and creep (Khanna, 2018).

High Temperature Tribological Properties

There is an increasing demand for high performance materials that can withstand extreme operational conditions experienced in modern industries and operations such as large loadings, high velocity moving contact components and high temperature operations. This has resulted in the emergence of research into high temperature tribological properties and applications of MMCs, due to the limitations presented by metals and alloys. The primary tribological parameters that controls the friction and wear behavior of MMCs include the mechanical and physical factors extrinsic to the material experiencing surface interactions such as sliding velocity, normal loading, surface finish and temperature. The material intrinsic factors such as MMC matrix microstructure, reinforcement type, size and reinforcement shape and amount will also control the tribological performance. Temperature is one of the important key parameter influencing the tribological properties of MMCs. The effect of temperature on the tribological behavior due to changes in sliding speeds and normal loads have demonstrated that the wear performance is directly influenced by the composite thermal properties namely; the thermal conductivity of the matrix as well as the reinforcement (Vissutipitukul and Aizawa, 2005). It has also been noted that the presence of composite defects such as voids and porosity can reduce the mechanical and tribological properties of MMCs (Naplocha and Granat, 2008). Generally, a material is considered to possess good tribological behavior if it has either a low value of coefficient of friction or if it has low wear rate indicating that the degradation rate was low.

Frictional Behavior

It is generally established that almost all real surfaces no matter how carefully prepared are rarely smooth. They are gently undulating and consist of macroscopic and microscopic asperities. The friction between such surfaces in contact emanates from the interaction at these points of asperities where actual or true contact takes place. During these interactions, there will be adhesion of

Fig. 8 Variations of coefficient of friction with temperature for Al based alloys. Reproduced from Menezes, P.L., Ingole, S.P., Nosonovsky, M., Kailas, S.V., Lovell, M.R., 2013. Tribology for scientists and engineers: From basics to advanced concepts. In: Tribology for Scientists and Engineers: From Basics to Advanced Concepts, vol. 9781461419457, Issue November. Available at: <https://doi.org/10.1007/978-1-4614-1945-7>.

surfaces at the contacting point then plastic or elastic deformation of the asperities by the load will occur. As a result the force required to overcome friction will entail the force required to shear the adhesion and to deform the obstructing asperities depending on the relative hardness of the surfaces involved (Tang *et al.*, 2008). The friction force required consist of two forces, the force to shear the adhesion of asperities and the force to elastically or plastically deform the obstructing asperities.

The value used to show the relationship between two object in contact and the normal reaction between the objects is referred to as “coefficient of friction”. The coefficient of friction of MMCs varies significantly from one another depending on a combination of many factors such as sliding speed, loading, reinforcement content and other parameters influence properties (Ceschini *et al.*, 1998). A typical example of the friction behavior of MMCs is depicted in Fig. 8 showing the variation of the friction coefficient with temperature for aluminum matrix composites. The values of the friction coefficient are initially constant until a certain temperature then there is an increase in coefficient of friction value as the temperature increases. It can be inferred that this observation is due to the softening effect of the heat on the matrix material thereby reducing the composite overall hardness. Many researchers have determined different values of friction coefficient with respect to temperature variations (Veličković *et al.*, 2016), however, some result correlate with each other while other values contradict observations of others and hence no general rule can be deduced. However, due to the high value of hardness and strength of the MMCs induced through reinforcement, the values of coefficient of friction for MMCs are relatively lower than that of metals and metal alloys.

Wear Behavior

Wear is the irreversible and progressive loss of materials during relative motion between contacting bodies (Lancaster, 1989). Due to the significant number of operating inefficiencies and economic losses in engineering assemblies sustained through this wear degradation phenomenon, extensive tribological investigations on MMCs have been carried out by various researchers (Leng *et al.*, 2009; Choi *et al.*, 2010). The general observations indicate better wear performance for MMC compared to that of materials with unreinforced matrices. During the wear test, the asperities of the unreinforced material plastically deforms hence an increase in wear while for reinforced matrices there is increased wear resistance due to the delayed plastic deformation of asperities. This is attributed to the improved strength due to the load bearing embedded particles in the composites. Some researchers have indicated that an increase in the content of the reinforcement material into the matrix can further reduce material loss through wear degradation as shown in Fig. 9. As an example, the wear rate of the Al6061 decreases as the amount of SiC reinforcing particles are added to the matrix. Baradeswaran and Elaya Perumal (2013); Tee *et al.* (2000) and Shipway *et al.* (1998) also demonstrated in their studies that there was a noticeable reduction in the wear rate as the content of reinforcing materials was increased in the composite matrix.

The effect of temperature on the wear performance of MMCs have been of significant concern. The sliding wear behavior of MMCs is important whenever relative motion is concerned. The motion can be intentional such as in the case of machining and automotive brake disks, it can also be unintentional like in the fretting wear of a joint. In some operations MMCs are exposed to tribo-contact at elevated temperatures hence the need to comprehend the thermal influence on tribological performance. Such investigations have established that there exist a critical temperature at which the coefficient of friction and the wear rate changes (Ceschini *et al.*, 1998; Tang *et al.*, 2008). Below this critical temperature the wear rate of MMCs initially decreases with an increase in temperature. After critical temperature is reached, the wear rate increases as the temperature further rises resulting in catastrophic wear (Martín *et al.*, 1996). The initial increase in wear performance can be attributed to an increase in ductility as the sample temperature is increased thereby limiting the crack formation and propagation. The extremely low wear resistance at high contact

temperatures can be expected as the material experience some degree of surface melting as well. A typical example of the wear performance behavior of MMCs is depicted in Fig. 10 showing the variation of the wear rate with temperature for aluminum matrix composites. It can also be inferred that the variation of the wear rate of MMCs with temperature is dependent on mechanical properties of the materials at high temperatures. However, some composites such as Ni-Cr-W-Fe-C-MoS₂ have self-lubricating properties at elevated temperatures due to the solid lubricating effects of molybdenum disulfide and graphite (Li and Xiong, 2008; Sun *et al.*, 2013). In such composites, at temperatures above 400°C, the graphite oxides forming a layer that complement the lubricating effect of the molybdenum sulfide thereby improving wear performance of the composite as the temperature increases.

High Temperature Thermal Properties

Specific Heat Capacity

Material selection and synthesis for high temperature applications requires scientists and engineers to understand and determine thermal properties. Heat capacity, thermal conductivity and thermal expansion are critical properties often utilized for solids such as MMCs. The heat capacity also known as the thermal capacity is a physical property of matter, defined as the amount of heat added to an object resulting in a unit change in its temperature (Almadhoni and Khan, 2015). Since the total heat a material can

Fig. 11 Thermal properties of Al-SiC composite; (a) variation of specific heat with respect to temperature and (b) variation of CTE with respect to temperature. Reproduced from Menezes, P.L., Ingole, S.P., Nosonovsky, M., Kailas, S.V., Lovell, M.R., 2013. Tribology for scientists and engineers: From basics to advanced concepts. In: Tribology for Scientists and Engineers: From Basics to Advanced Concepts, vol. 9781461419457, Issue November. Available at: <https://doi.org/10.1007/978-1-4614-1945-7>.

absorb or dissipate is dependent on also volume or mass a parameter called specific heat defined as the heat capacity per unit mass is utilized. The specific heat of MMCs is dependent on a number of factors such as reinforcement materials, reinforcement content, matrix material and temperature of operation. For example, Fig. 11(a) shows the variation of specific heat of aluminum based MMC with respect to temperature, it shows that the specific heat capacity increases with increased temperature and with increase in the volume percentage of the aluminum reinforcement.

Thermal Expansion

Thermal expansion is the tendency of matter to experience change in volume in response to temperature variations (Vaidya and Chawla, 1994), generally materials increase volume as the temperature increases. Therefore, the thermal expansion of materials is generally expressed as fractional change in material dimensions per unit temperature change. The expansion in matter can be described in terms of Coefficient of Thermal Expansion (CTE). In MMCs the CTE is a significant parameter which influences the stability of composites at elevated temperature ranges. MMCs are highly valued for their high temperature operations and find potential applications in thermal environments such as automobile parts, brake rotors and drive shafts. These materials should have sufficient thermal stability that is to be resistant to severe geometric changes and mechanical property alterations during thermal loading. This is depicted by a graph in Fig. 11(b) showing a small increase in CTE as the temperature is increased. For greater thermal performance of MMCs, they should have lower CTE. Generally, in the absence of phase interactions the CTE of a material at a particular temperature can be expressed as:

$$CTE = \frac{\partial}{\partial T} \left(\frac{\Delta L}{L} \right) \quad (3)$$

where L represents the length of the materials and T is the temperature of the specimen. For solid material, the linear coefficient of thermal expansion $\overline{CTE}$ can be used and calculated by the formula:

$$\overline{CTE} = \frac{1}{L_0} \left(\frac{\Delta L}{\Delta T} \right) \quad (4)$$

where L_0 is the original length and ΔL is the change of length over temperature interval ΔT .

However, due to the existence of different materials within a composite, there is a high possibility of a mismatch between the CTE of the composite matrix material and the reinforcement material. The inherent thermal mismatch between the composite matrix and the reinforcement material can induce the development of residual stresses and the consequent damage or crack initiation and progression, potentially weakening the microstructural integrity and performance of composite structures (Vaidya and Chawla, 1994). Expressions for the CTE of composite with considerations of the matrix and reinforcement material stress interactions have been proposed in several investigations (Fei and Wang, 2004; Kim *et al.*, 2001; Vaidya and Chawla, 1994).

According to the Turner model, in order to analytically determine the CTE of composite materials, the following equations are to be used:

$$\alpha_c = \bar{\alpha} + V_p (1 - V_p) (\alpha_p - \alpha_m) \times \frac{K_p - K_m}{(1 - V_p) K_m + V_p K_p + \frac{3K_p K_m}{4G_m}} \quad (5)$$

Where:

$$K = \frac{E}{3(3 - \frac{E}{G})} \quad (6)$$

$$\bar{\alpha} = (1 - V_p) \alpha_m + V_p \alpha_p \quad (7)$$

where α_c represents the composite CTE, V_p is the value of the reinforcement component fractions, E and G are the longitudinal and transversal elastic modules of the matrix and the reinforcing elements, respectively.

Thermal Conductivity

Thermal conductivity of a materials is the rate at which a material transfers heat by conduction through a given unit area (Dash *et al.*, 2016). In general, the higher the thermal conductivity the higher the heat transfer rate and vice versa. Just like other thermal properties of MMCs, the thermal conductivity of a composite material depends on the operating temperature, direction of the heat flow, reinforcement volume fraction, particulate type, distribution of the reinforcements and its size. Due to the interfacial thermal barrier resistance in composites, the thermal conductivity depends on both the volume fraction of the dispersed phases as well as on the dispersion size. However, interfacial thermal barriers are expected to be effective only if they are nonparallel to the direction of heat flow. For the thermal conductivity of MMCs containing micro particles the shape and volume of the incorporated particles should be taken into consideration. Thermal boundary resistance due to the presence of pores and voids plays a significant role in lowering the thermal conductivity of composites. Furthermore, finer particles of SiC in the composite have been found to cause a considerable decline in thermal conductivity, this is because there is an increased contribution of interface to thermal resistance as particles becomes smaller.

Thermal Fatigue (Thermo-Mechanical Property)

Fundamental understanding of fatigue behavior of MMC is of great significance since they are widely featured in engineering applications that are exposed to thermal cyclic loadings due to thermal expansions and thermal contractions during service (Llorca, 2002). The main cause of thermal fatigue in MMCs is the cyclic change of temperature and complete or partial restriction of thermal deformation due to external or internal limitations, which can lead to fatigue cracking at locations with stress concentration. Generally, at elevated temperatures, the fatigue behavior of reinforced MMCs is governed by the cyclic softening and the cyclic hardening processes. The cyclic hardening process occurs through the formation and interaction of new dislocations in the matrix whereas the cyclic softening process is due to interface failure, precipitate coarsening, matrix cavitation, and the rearrangement and annihilation of dislocations (Wu and Han, 2006). At elevated temperatures MMCs mainly experience cyclic softening due to the reduction of strength in the matrix material. However, the thermal fatigue performance of the MMC can be improved by decreasing particle size and increasing the reinforcement volume fraction.

Thermal Shock Resistance

Thermal shock occurs when a material undergoing sudden changes in temperature develops internal stresses and strains that may cause cracking and eventually failure (Douin *et al.*, 2002). The resistance of MMCs to thermal shock is closely linked to its mechanical strength as shown in Eq. (8). When subjected to alternating thermal loadings, the internal stresses responsible for crack formation and propagation are formed. Under thermal loading, a material is placed under a high compression due to the high surface temperature and a large temperature gradient. This will result in viscoplastic deformations in order for the stresses to relax. Consequently, upon cooling, tensile internal stresses are generated in the composite and in turn initiate and or propagate surface cracks. Generally, materials with reinforcement demonstrate much better strength properties at elevated temperatures due to their increased thermal shock resistance (Daehn *et al.*, 1993; Ho and Saigal, 1994). In practice, thermal shock resistance is characterized

by temperature variation ΔT determined on the basis of heating and cooling cycles and expressed as follows.

$$\Delta T = \frac{\sigma(1 - \nu)}{E\alpha} \quad (8)$$

where α , σ and ν are the coefficient of thermal expansion, cracking stress and Poisson ratio respectively. The estimation of the Poisson ratio and elasticity modulus of composite can be determined using a mixing rule:

$$\nu_c = \nu_m \phi + \nu_r(1 - \phi) \quad (9)$$

$$E_c = E_m \phi + E_r(1 - \phi) \quad (10)$$

where the mean volume of fraction is denoted by ϕ , while c, m and r represent indices identifying composite, matrix and reinforcement respectively.

High Temperature Electrical Properties

Electrical Conductivity and/or Resistance

One of the important and ever-growing applications of high temperature MMCs is in electrical and electronic applications which is due to their electrical resistivities and conductivities (Chang *et al.*, 2003). However, for this application both the metal matrix and the reinforcement must have a similar CTE to minimize distortion that may arise due to mismatching thermal expansion as a result of the heating effect of current flow. One of the most used MMCs in power transmission cables is made from aluminum reinforced with alumina obeys this (Haghshenas, 2016). Electrical resistivities of MMCs are reported to be a function of the volume fraction of the reinforcement used. This behavior is mostly observed on Ag/SiC, Al/SiC, Cu/SiC and Mo/SiC composites, increasing the volume fraction of the reinforcement tends to increase the residual stresses and the dislocation density of the composite (Chang *et al.*, 2003).

Electrical conduction in MMCs is affected by the interfacial electrical resistance at the interface between the matrix and the reinforcement, this only applies if the current moves across the interface. Interfacial layer thickness heavily decreases the electrical conductivity by increasing the resistivity (William Clyne, 2017). In addition, oxide films, pores and inclusions that result from processing of the MMCs also influence the electrical conductivity of the MMCs.

Concluding Remarks

- Metal–matrix composite materials (MMCs) have been studied for two decades initially stimulated by the high performance needs of the aerospace industry. Currently, their use span across a wide range of engineering applications due to their excellent tribological properties, high mechanical properties at elevated temperatures, low coefficient of thermal expansion and high transverse stiffness.
- MMCs are characterized by low friction coefficient and excellent wear resistance compared with the unreinforced matrix due to the hardening effect of the reinforcing particles as well as the lubricating effects of solid lubrication phases such as graphite and disulfide particles.
- High temperature properties of MMCs are generally governed by the composite matrix material, reinforcement material, reinforcement volume fraction, size and distribution, operating temperature and the direction of the heat flow.
- Research into metal matrix composites is fascinating and offers endless possibilities; different matrix-reinforcement mixtures, variations of synthesis methods and parameters, reinforcement orientations and volume fractions will result in different properties, therefore the knowledge offers scientist and engineers the ability to tailor the composite for specific applications of choice.

MMNC Metal matrix nanocomposite.

Introduction

Creep is the plastic deformation of a material at a stress below the yield strength, at elevated temperature and over a long period of time. Elevated temperature in this case means $>0.4 T_m$, since below this temperature thermally activated deformation processes are not significant. The experimental mapping of the creep behavior of a material is carried out in creep tests in which the creep deformation is plotted as a function of the time of creep testing. The first derivative of this curve describes the creep rate. Creep tests are carried out either with tensile, compression, or shear deformation, depending on the real load case in which the material is used. Since the creep curves are recorded at a constant temperature, it should be noted that continuous sustaining of the deformation mechanisms can only be guaranteed at a constant stress. If, on the other hand, measurements are taken at a constant load, it is clear that the stress increases in the tensile creep test because the specimen cross-section decreases while it decreases in the compression creep test because the specimen cross-section increases. This changes the boundary conditions during the test and is therefore not recommended for mechanism-oriented design of experiments.

Often, but not always, creep tests show three regions. After an instantaneous deformation during the application of stress, which consists of elastic and plastic components, Phase 1 follows, in which the strain rate decreases after rapid deformation. The material undergoes strengthening in this time until a minimum strain rate is reached. This is where the second phase of the creep test begins, in which a constant deformation rate, known as the secondary creep rate, is reached. This secondary creep rate is also referred to as minimum creep rate, and here strengthening and de-strengthening processes in the material are equalized. The first two phases take place both in the tensile creep test and in the compression creep test. The third phase, in which the creep rate increases again because the de-strengthening mechanisms overtake and the sample is necked, can only be found in the tensile creep test. The third phase ends here with the failure of the sample. Only at very high stresses can such an effect occur in the compression creep test. Fig. 1 shows the typical curves of tensile and compression creep and the corresponding strain rate curves.

There is in principle an infinite number of combinations of the parameters "temperature" and "stress" for performing creep tests. This of course results in the fact that only creep tests performed at identical temperatures and stresses on two or more materials are comparable in order to answer the question of which material is more creep resistant. However, the answer then only applies to these selected parameters; at other temperatures or stresses, another material may well be more suitable for an application.

The dependence of the individual variables temperature (T) and stress (σ) is indicated in Fig. 2. With increasing temperature at constant stress or with increasing stress at constant temperature the initial deformation and the secondary creep rate increase and time to rupture decreases.

Since the secondary creep range is the dominant time span, the secondary creep rate plays an important role in the evaluation of creep tests. This secondary creep rate $\dot{\epsilon}_s$ depends on the temperature, the applied stress, and of course the tested material.

Usually, a power law describes the dependence of the minimum creep rate on the applied stress. This applies to

$$\dot{\epsilon}_s = A\sigma^n \quad (1)$$

Here, A is a temperature-dependent material constant and n is the stress exponent, which allows for estimations about the rate determining deformation mechanisms. However, since creep is a thermally activated process, just like diffusion itself, temperature dependence can be described simultaneously using an Arrhenius approach. Together with Eq. (1) this results in:

$$\dot{\epsilon}_s = A \exp\left(-\frac{Q_c}{RT}\right) \sigma^n \quad (2)$$

Here, R is the gas constant, Q_c the activation energy for creep.

Fig. 1 (a) Examples of creep curves from tensile and compression creep tests and (b) the resulting strain rate curves.

Fig. 2 Change of creep curve with increasing temperature or stress.

Different deformation mechanisms can determine the rate by which creep occurs. Their influence on the creep rate depends on the applied stress and temperature. The main mechanisms are described below.

Diffusion Controlled Creep

All deformation mechanisms can be described with the help of a strongly generalized basic equation into which the material parameters flow (Langdon, 2002). Eq. (3) represents the secondary creep rate as a function of environmental conditions and material properties.

$$\dot{\epsilon}_s = \frac{ADGb}{kT} \left(\frac{b}{d}\right)^p \left(\frac{\sigma}{G}\right)^n \quad (3)$$

G is the shear modulus, b is the Burgers vector, d the mean grain diameter, k the Boltzmann constant, p and n the exponents, which are based on grain size and stress and D is the temperature-dependent diffusion coefficient:

$$D = D_0 \exp\left(\frac{-Q_c}{RT}\right) \quad (4)$$

All described simple relations can be traced back to this equation, and the following mechanisms can be represented by suitable choice of parameters in the form of this equation.

The following diffusion-based creep mechanisms are dominant when high temperatures and low stresses are acting.

Fig. 3 (a) Schematic of the Nabarro–Herring mechanism for diffusion creep and (b) areas of the Coble (C.) and Nabarro–Herring (N.H.) creep in the opened space of temperature, creep rate, and grain size. Reproduced from Poirier, J.P., 1985. *Creep of Crystals: High-Temperature Deformation Processes in Metals, Ceramics and Minerals*. Cambridge, NY: Cambridge University Press.

Nabarro–Herring Creep

Nabarro (1948) and Herring (1950) discovered this mechanism independently of each other and established almost identical equations to describe the dependence of creep rate and stress. The model is based on the migration of vacancies as shown in Fig. 3.

Starting from a tensile load in vertical direction, the vacancy concentration is higher in the areas marked with 1 in the central grain than in the areas marked with 2. The reason for this is the grain boundary under tensile load, which thus represents a source of vacancies, since the energy required to generate a vacancy equals the amount σb^3 , where b^3 is the volume of an empty space. The grain boundaries at 2 have a formation energy increased by the amount σb^3 for a vacancy, which makes these areas vacancy sinks. The vacancies will therefore move into the areas marked with 2 (arrows). This is equivalent to an atom movement in the opposite direction and leads to an extension of the grain in the tensile direction. The model can also be applied identically to an externally applied compressive load from the side. The relationship between minimum creep rate and stress in Nabarro–Herring creep corresponds approximately to Eq. (5):

$$\dot{\epsilon}_s = \frac{ADGb}{kT} \left(\frac{b}{d}\right)^2 \left(\frac{\sigma}{G}\right) \quad (5)$$

Here $D = D_0$, i.e., the diffusion coefficient for self-diffusion in a lattice.

A first proof for the existence of the Nabarro–Herring mechanism were investigations by Weiner *et al.* (1963), in which creep investigations were carried out on an Mg-0.5Zr alloy. At temperatures of 450 and 500°C and loads of 0.76 and 1.37 MPa, areas free of Zr were visible near the grain boundaries. These areas were only at grain boundaries perpendicular to the tensile direction. A directional diffusion of the magnesium towards the grain boundaries was the explanation for the appearance of these areas.

Harris and Jones (1963) computed from the width of the resulting diffusion zones the elongation of the specimen and came to a good consistency with the theory formulated by Herring.

Coble Creep

Coble (1963) investigated the phenomenon of diffusion-controlled creep in polycrystalline material. In contrast to volume diffusion with Nabarro–Herring, the Coble mechanism is controlled by grain boundary diffusion. The creep rate in Coble creep is not dependent on the inverse square of the grain diameter, as in Nabarro–Herring creep, but on the inverse third power of the grain diameter. In Eq. (6), $D = D_{GB}$. Since the activation energy for grain boundary diffusion is (GB) smaller than for lattice or vacancy diffusion, Coble Creep occurs at lower temperatures than Nabarro–Herring creep, see Fig. 3(b).

$$\dot{\epsilon}_s = \frac{ADGb}{kT} \left(\frac{b}{d}\right)^3 \left(\frac{\sigma}{G}\right) \quad (6)$$

Harper–Dorn Creep

Harper and Dorn (1957) investigated both aluminum single crystals as well as polycrystalline aluminum in the range of low stresses close to the melting point. The result was a stress exponent of $n = 1$, but creep rates significantly higher than those to be derived from the Nabarro–Herring mechanism. In addition to this deviation from the predicted secondary creep rates, another difference became apparent. The creep rates in both the polycrystalline material and the single crystals showed virtually no dependence on grain size, which is the case in both the Nabarro–Herring and Coble mechanisms. Ardell and Lee (1986)

confirmed these results in experiments carried out on aluminum single crystals under pressure. This results in a creep mechanism that obeys Eq. (7). It is $n = 1$ and $p = 0$.

$$\dot{\epsilon}_s = \frac{ADGb}{kT} \left(\frac{\sigma}{G} \right) \quad (7)$$

Dislocation Creep

The predictions of the minimum creep rates at high temperatures and low stresses can be made with the diffusion-based descriptions mentioned above. Thus, it seems that diffusion-controlled mechanisms determine the rate of creep. At higher stresses, however, the measured minimum creep rates are higher, so further mechanisms dominating the creep rate must become effective. These are processes based on dislocation motion. Irrespective of the metal, grain size, lattice constants, lattice structure (hcp, fcc, bcc), etc., creep curves of all pure metals or alloys are very similar, which suggests that fundamental phenomena, such as strain hardening, recovery, and internal stresses, are regarded as overarching framework conditions irrespective of dislocation theories (Evans and Wilshire, 1993).

Dislocation Climb and Glide

Dislocation creep is the result of dislocations moving through the material causing plastic deformation. There are two basic types of dislocation motion, climb and glide as is depicted in Fig. 4. Weertman (1955) developed a first model in 1955 that explains a power law creep with a mechanism based on climbing dislocations. The dislocations climb over obstacles by creating and destroying vacancies.

Dislocation motion may be obstructed by precipitates, grain boundaries, other dislocations and solute in solid solution (von Buch *et al.*, 2002). Weertman assumes that the obstacles are non-mobile dislocations as described by Lomer (1951). Solute in solid solution may also slow the kinetics of dislocation motion through solute drag (Mordike, 2002; Gittus, 1974). The seminal work by Cottrell and Jaswon (1949) described that the speed of the dislocation motion is limited by the migration rate at which solute atoms glide in the slip plane and slip direction of the dislocation. It is possible, at relatively high temperatures, for dislocations to avoid those obstacles through the thermally activated process of dislocation climb (Ashby, 1972). Climb or non-conservative motion occurs perpendicularly to the direction and plane of gliding. Weertman (1957) slightly corrected the assumptions that were required for the first model and developed an extended model that could be better reconciled with measured creep rates of polycrystalline aluminum, but also describes a power law creep. The dislocations generated at Frank–Read sources accumulate at obstacles and interact with accumulations generated by other sources from parallel slip planes. If the material is exposed to a constant load, inhomogeneities occur, the compensation of which in turn leads to deformation. The creep rate is thus proportional to the number of dislocation sources N and the climbing rate of the dislocations, but inversely proportional to the distance between two adjacent accumulations of dislocations. This results in the following expression for the minimum creep rate:

$$\dot{\epsilon}_s = \frac{BD_s\sigma^{4.5}}{b^{0.5}N^{0.5}G^{3.5}kT} \quad (8)$$

The constant B is in the order of 0.2 (Lagneborg, 1972).

Fig. 4 (a) Dislocation glide, the arrows indicate the applied shear stress and the numbers indicate the movement of atoms, (b) dislocation climb, in (2) the dislocation is centered in row A and is shown to climb in a positive sense in (1) and negative in (3) via diffusion of atoms and vacancies. Fig. 5 Grain boundary sliding revealed through the use of a transverse marker line across grain boundaries for a Mg-0.78Al (wt%) alloy creep tested at 17.2 MPa and 200°C. Reproduced from Langdon, T.G., 2006. *Journal of Materials Science* 41, 597.

Grain Boundary Sliding (GBS)

Grain boundary sliding (GBS) is defined as the relative movement of two adjacent grains as a result of an applied stress (load) at which the movement takes place within the grain boundary or at least in its direct vicinity. This definition is taken from a review paper by T.G. Langdon, which addresses the GBS as a deformation mechanism during creep (Langdon, 2006). The two different mechanisms that can occur in GBS are explained. On the one hand there is Racher gliding, in which dislocation movement occurs within the grains, and Lifshitz gliding, which is based on diffusion processes in Nabarro and Coble creep. GBS has been observed in different metals mostly by lines scratched on a polished surface and showing a step at the grain boundaries after creep (Fig. 5).

The dependence of the deformation rate of GBS is also described. Already in 1970, Langdon (1970) formulated the dependence of the minimum creep rate being proportional to σ^2/d , resulting in the following equation, where $n = 2$, $p = 1$ and $D = D_L$.

$$\dot{\epsilon}_s = \frac{ADGb}{kT} \left(\frac{b}{d}\right)^1 \left(\frac{\sigma}{G}\right)^2 \quad (9)$$

In the following sections, methods used to help reinforce metal alloys against creep will be discussed. The methods described primarily use additional components such as particle or fiber reinforcements to help minimize the influences of the aforementioned creep mechanisms.

Creep of Particle-Reinforced MMCs

The particle-reinforced metal matrix composites (MMCs) are of importance due to their promising applications in automotive and aerospace industries at elevated temperatures (Peng and Zhu, 2003; Dieringa, 2011, 2018). The most widely used particles in MMCs are ceramic particles, such as SiC (Wang *et al.*, 2014; Aravindan *et al.*, 2015), Al_2O_3 (Hassan and Gupta, 2005; Sameer *et al.*, 2017), AlN (Saboori *et al.*, 2017), and Y_2O_3 (Han and Dunand, 2001). They are extensively utilized to enhance the matrix because of their low costs, high hardness, and high thermal stabilities at elevated temperature (Ye and Liu, 2004). These particles have the ability to improve not only the mechanical strength and ductility, but also creep resistance at elevated temperature (Goh *et al.*, 2007; Kumar and Chaudhari, 2014). According to the size of particles, the MMCs can be divided into two groups: Micro-sized particle and nano-sized particle reinforced MMCs.

Micro-Sized Particles

Labib *et al.* (2015) researched the creep properties of pure Mg and its composites with additions of 5, 7.5, 10 and 15 vol% SiC particles (10 μm) prepared by powder metallurgy and extrusion processes. The creep tests were performed under stresses ranging from 150 to 250 MPa in a temperature range of 423–473K. Fig. 6 shows that the optimum volume content of SiC particles for creep resistance in Mg alloy is 10 vol%. With further increasing content of SiC particles up to 15 vol%, there is a slight decrease in the creep resistance due to the occurrence of small clusters in the microstructure. The enhancement of the creep resistance is ascribed to the effective load transfer from the matrix to the particles and thermal mismatch between Mg matrix and reinforcements. The stress exponents of Mg and its composites are in a range of 7.0–7.9 and the activation energy values are similar to the lattice self-diffusion (92 kJ mol^{-1}), suggesting that the controlling creep mechanism could be dislocation climb by pipe diffusion.

Viswanath *et al.* (2015) studied the creep behavior of AZ91 (Mg-9.3Al-0.8Zn-0.18Mn) matrix with the reinforcements of 5, 10, 15, 20, and 25 wt% SiC particles ($\sim 23 \mu\text{m}$) at 175°C (448K) under constant stresses of 80, 100, and 120 MPa. Fig. 7 reveals that there are no obvious differences on the minimum creep rate when the content of SiC particles is below 10 wt%. However, when

Fig. 6 Variation of normalized minimum impression velocity with vol% of particles at different punching stresses for the materials tested at (a) 423K, (b) 448K and (c) 473K. Reproduced from Labib, F., Mahmudi, R., Ghasemi, H.M., 2015. Materials Science and Engineering: A 640, 91.

Fig. 7 Minimum creep rate vs. (a) applied stress and (b) effective stress. Reproduced from Viswanath, A., Dieringa, H., Ajith Kumar, K.K., Pillai, U.T.S., Pai, B.C., 2015. Journal of Magnesium and Alloys 3, 16.

the addition of SiC particles is up to 15 wt%, a significant improvement on the creep resistance was revealed. The true stress exponents of AZ91 and its composites were calculated in a range of 5.4–5.8, which demonstrated that the dominant creep mechanism is related to dislocation climb at elevated temperature. They suggested that the addition of hard SiC particles could impede the grain boundary sliding and the dislocation movement, which is beneficial to the creep resistance in AZ91 alloy.

It is also reported that the addition of ceramic particles could result in a decrease of the texture after extrusion (Garcés *et al.*, 2006) and thus influence the creep behavior. Garcés *et al.* (2007) fabricated Mg with the additions of 5 vol% Y_2O_3 particles (6 μm) by a powder metallurgy process and extruded at 400°C with an extrusion ratio of 20:1. Creep tests were conducted at an initial strain rate of 10^{-4} s^{-1} to reach a steady state between a temperature range of 100–500°C to obtain the stress exponent. They found that the creep resistance of unreinforced Mg is higher than reinforced Mg when the temperature is below 300°C, while its creep resistance became lower than reinforced Mg for the temperature above 300°C. For the low temperature regime (below 300°C), the creep resistance was controlled mainly by the fiber texture. It is reported that the grain orientation and ceramic particles could both contribute to the yield stress σ with this following equation:

$$\sigma_y^{comp} = A(\sigma_y)_{Tex.} + B(\sigma_y)_{Reinf} \quad (10)$$

The texture intensity for unreinforced Mg is higher than for reinforced Mg. Therefore, the creep deformation controlled by the dislocation slip is not easy to be activated in the unreinforced Mg and gives a higher creep resistance in this material. For the high temperature regime (up to 300°C), the enhancement of creep resistance from the Y_2O_3 particles became more effective in reinforced Mg, which results in a higher flow stress compared with that of unreinforced Mg.

Liao *et al.* (2010) studied the influence of T6 heat treatment on the creep resistance of Al8090 (Al81-SiCp15-Li2-Cu1.20-Mg0.80) with the addition of β -type SiC particles fabricated by spray-deposition. The creep properties were tested over a stress range of 15–150 MPa at four different temperatures (250, 300, 350, and 400°C). They found that the creep resistance of T6-aged specimen was obviously higher than that of the as-received specimen by 2–3 orders of magnitude. This is attributed to the small precipitates, that is δ' (Al_3Li)

Fig. 8 The representative creep curves for (a) A359 and (b) A359/SiC/10P at 573K. Reproduced from Hamed, O.A., Shady, M., El-Desouky, A., 2001. Materials & Design 22, 473.

and S (Al_2CuMg) phases formed in the heat treated materials. They have small inter-particle spacing, which can effectively transfer the load from the matrix and enhance the creep resistance. The non-heat treated composite has a stress exponent of approximately 5. This is ascribed to the occurrence of many Cu and Mg-rich intra-granular second phases, which depletes the solid solution of these alloys. Meanwhile, the processing condition also influences the creep behavior in Al alloys, where the spray-deposited Al8090 composite has much higher creep resistance than that reported in Al2124, 6061, 7005, and 8090 prepared by powder metallurgy (PM) and liquid metallurgy (LM) methods.

The processing parameters during fabrication also influence the distribution of the particles and its creep behaviors. Hamed *et al.* (2001) added 11 vol% SiC particles with an average size of about 20 μm in Al-9Si-0.6Mg (A359) by ultrasonic stirring to study its tensile creep properties. Creep tests were conducted at 573K under different stresses between 40–60 MPa. It is found that the low melting temperature (735°C), 5 min stirring time and high solidification rate can lead to a fine dendrite arm spacing and uniform distribution of particles without any visible porosities in the composite. The formation of the Al_4C_3 phase was suppressed by the SiC particles under this processing condition. The creep curves reveal that the SiC particle-reinforced composites show better creep resistance than that of unreinforced materials under the same creep condition (Fig. 8). This is attributed to the coefficient of thermal expansion between the A359 matrix and the SiC particles, which can cause a high density of dislocations around the SiC particles during creep and increase the creep properties. They also found that the threshold stress σ_{th} decreases with increasing temperature and even disappears when the temperature is up to 750K. It is suggested that two mechanisms are related to this phenomenon: Load transfer and dislocation long range internal back stresses.

Nano-Sized Particles

It is reported that the addition of nanoparticles (NPs) could influence the formation of second phases in the matrix. Ganguly and Mondal (2018) reported on the 2.0Ca + 0.3Sb (wt%)-containing AZ91 alloy with additions of 0.5, 1.0, and 2.0 wt% SiC NPs

(average size of 50 nm) by squeeze-casting, respectively. The impression creep tests are carried out in the stress range of 300–480 MPa and a temperature range of 448–523K. They found that α -Mg, β -Mg₁₇Al₁₂, Al₂Ca, and Ca₂Sb phases were formed in the nanoparticle-free alloys. By adding SiC NPs, the formation of β -Mg₁₇Al₁₂ was suppressed while the phase fraction of Al₂Ca was increased, especially when the content of SiC NPs is 2.0 wt%. The creep rates of the composites show that the addition of SiC can effectively increase the creep resistance of a 2.0Ca + 0.3Sb (wt%)-containing AZ91 alloy and 2.0 wt% SiC shows the best creep resistance among all the materials. The stress exponents of these composites are in a range of 4.5–6.2 and the activation energies are 101.9 ± 2.5 to 115.5 ± 3.2 kJ mol⁻¹, indicating that the dominant mechanism is dislocation climb controlled by pipe diffusion during creep. This excellent creep resistance for these composites results from the increasing fraction of thermally stable Al₂Ca phase and SiC NPs, which can effectively hinder the dislocations and contribute to the superior creep resistance for the composites.

Kumar and Chaudhari (2014) studied the creep behavior on the commercially available AS41(Mg-4Al-Si) alloy with 2 and 5 wt% nano-alumina (50 nm) prepared by a combination of stir casting and ultrasonic treatment. The impression creep tests were performed at 448, 473, 498, and 523K under three constant stresses: 109.2, 124.8, and 140.4 MPa. The creep curves show that the addition of Al₂O₃ can obviously increase the creep resistance of AS41 alloy. With the increasing content of Al₂O₃ NPs, the creep resistance was increased accordingly. The calculations of stress exponents for AS41, AS41/2 wt% and AS41/5 wt% are in a range of 3–6.5, suggesting that the dislocation creep is the dominant creep deformation mechanism for AS41 and its composites. The activation energies for AS41, AS41/2 wt% and AS41/5 wt% are 66.17, 83.77, and 88.3 kJ mol⁻¹, respectively, which is close to the pipe diffusion of Mg (92 kJ mol⁻¹). They proposed that the improvement of creep resistance is ascribed to the following factors: (1) by adding nano-Al₂O₃ in AS41 alloy, the intermetallic phases were distributed evenly throughout the matrix, i.e., Mg₁₇Al₁₂ and Mg₂Si, due to the assistance of ultrasonic treatment. However, in the as-cast AS41, the intermetallics were mainly formed along the grain boundaries. (2) The strengthening effect from the nanoparticle reinforcements could also improve the creep properties of AS41 composites. Al₂O₃ NPs could (1) transfer load from matrix, (2) increase dislocation density due to the thermal expansion mismatch with the Mg matrix, and (3) hinder dislocation movement due to Orowan strengthening.

In order to investigate the effect of NPs on the creep properties in Mg-based alloys, Katsarou *et al.* (2016) fabricated the Mg-2.8Nd-1.2Gd-0.4Zr-0.3Zn (El21) alloy with and without 1 wt% AlN NPs by mechanical and ultrasound-assisted stirring. They conducted the compression creep tests at 240°C under the constant stresses range from 70 to 200 MPa. The creep curves show that its creep property was significantly improved compared with that of unreinforced El21 alloy with the addition of 1 wt% AlN NPs in El21 alloy. Its true stress exponents are in a range of 3.3–4.2, which corresponds to viscous glide of dislocation or dislocation climbing during creep. TEM characterization shows that the AlN NPs are agglomerated in the eutectic regions by the solidification front. Daudin *et al.* (2017) further studied the strengthening effect from the AlN NPs on the El21 alloy and proposed that the forest or Orowan strengthening from AlN NPs is unlikely to occur. Instead, there is an indirect influence from AlN NPs on the creep resistance. Micro-tomography characterizations display that AlN NPs can trigger the formation of dendrites in AlN-containing alloy and lead to a more branched intermetallic morphology, which may act as effective reinforcements in El21 alloy during creep (Fig. 9(b)).

Yang *et al.* (2019) fabricated the El21 alloy with 0.5 wt% AlN/Al NPs (25 wt% Al and 75 wt% AlN) with another method called high shear dispersion technique (HSDT). Creep tests were carried out at 240°C under the stresses between 70–140 MPa. It is found that the El21 + 0.5% AlN/Al NPs with the assistance of HSDT shows higher creep resistance than that of unreinforced El21 alloy (Fig. 10(a)). In particular, the HSDT plays an important role in enhancing the creep resistance of El21 alloy. El21 + 0.5% NPs sheared at 3000 rpm

Fig. 9 Micro-tomography slice of (a) El21 and (b) El21 with AlN NPs. Reproduced from Daudin, R., Terzi, S., Mallmann, C. *et al.*, 2017. Materials Science and Engineering: A 688, 76.

Fig. 10 (a) Creep rate vs. creep time and (b) minimum creep rate under different applied stresses for El21, El21-500, El21 + 0.5% NPs-500, El21-3000, and El21 + 0.5% NPs-3000, (c) the minimum creep rates compared with El21 + 1wt% AlN/Al prepared by ultrasonic (US) treatment and (d) the true stress exponent for all the materials. always shows lower minimum creep rate than that sheared at 500 rpm (Fig. 10(b)). Moreover, they suggested that HSDT is more effective to fabricate the NPs in El21 alloy than ultrasonic treatment in Katsarou *et al.* (2016). Fig. 10(c) shows that El21 + 1% NPs-3000 achieves a better creep resistance by HSDT than El21 + 1% NPs fabricated by ultrasonic treatment. The true stress exponent is in a range of 3.4–4.3, which is related to viscous glide of dislocation and dislocation climbing. It is concluded that the intermetallics became much thinner and more homogeneous at the grain boundaries and inside the grains, which can hinder the dislocation movement and cause the improvement on the creep resistance in AlN/Al reinforced El21 alloy (Fig. 10).

Creep of Short or Long Fiber Reinforced MMCs

Similar to micro or nano particle reinforcement, long or short fiber reinforced metals are also regarded as metal matrix composites (MMCs). The difference between long and short fibers is that long fibers may span the entire length of the cast material while short fibers are significantly shorter, on the order of 10's to 100's of microns in length. Long fiber reinforcement offers significantly higher amounts of reinforcement of the matrix compared to short fibers while short fibers are significantly easier to manufacture. However, both long and short fiber reinforced metals have been shown to have a marked improvement in the properties of the composite material.

Short Fiber Reinforced Composites

Tian and Shi (2014) showed that in an AZ91D alloy the additions of aluminum silicate ($\text{Al}_2\text{O}_3\text{-SiO}_2$) short fibers helped to improved creep resistance in comparison to AZ91D without reinforcement. The steady state creep rates of AZ91D reinforced with $\text{Al}_2\text{O}_3\text{-SiO}_2$ short fibers tested at three temperatures (473, 523, and 573K) all out performed the AZ91D alloy by at least an order of magnitude (Fig. 11). The improvement in creep properties was attributed to the load transfer from the alloy matrix to the short fibers.

Fig. 11 Double logarithmic relationship of steady-state creep rate and stress for (a) AZ91D alloy and (b) 30% $\text{Al}_2\text{O}_3\text{-SiO}_2(\text{sf})/\text{AZ91D}$ composite. Reproduced from Tian, J., Shi, Z.-Q., 2014. Transactions of Nonferrous Metals Society of China 24, 632.

The creep stress exponent value (n) was shown by Tian and Shi (2014) to be consistent between the standard and reinforced alloys. In both cases $n = 3$, viscous slip of dislocations was the primary controller. Thus, it was concluded that creep was a function of the matrix and the short fibers present successfully acted to transfer strain out of the matrix. A similar conclusion was made by Sklenicka *et al.* (2015) in AZ91 and QE22 alloys reinforced with 20 vol% Al_2O_3 (Saffil) short fibers. A stress load transfer between the matrix and the short fiber reinforcements was shown to be the cause of the creep property improvements. Sklenicka *et al.* (2015) showed that the presence of Saffil short fibers in AZ91 reduced the minimum creep rate by 2–3 orders of magnitude (Fig. 12). The QE22 + Saffil also had improved creep properties compared to the unreinforced QE22 but only at low stresses (≤ 100 MPa). From this result, it is clear that the addition of identical concentrations of short fiber reinforcement in different alloys has a noticeable effect on the alloy's properties. Furthermore, the presence of such reinforcement can hinder other material properties. In Sklenicka *et al.* (2015), the addition of Saffil led to a significant decrease in ductility of the matrix. This resulted in the fracture of both composite alloys to be only approximately 1%–2%.

The fiber–matrix interface is a key aspect to the effectiveness of short-fiber reinforcement for creep property improvement. In a work (Dieringa *et al.*, 2005) comparing the influence of 20% Saffil short fiber reinforcements in an AE42 (Mg-4Al-2 rare earth) alloy during tensile and compression creep, microstructural investigations on the interface between fiber and matrix were shown. There was nearly no fiber pullout at the fracture surface and furthermore the matrix surface showed ductile fracture behavior (Fig. 13). As a result of this good bonding behavior between fiber and matrix, the calculated tensile threshold stress (σ_0) at 300°C and 50 MPa of AE42 + Saffil was 30 MPa. In compression creep the AE42 + Saffil achieved a σ_0 which was approximately 23 MPa higher than that of the tensile creep. These relatively good elevated temperature creep properties were again attributed to the redistribution of stress from the matrix to the reinforcement fibers.

The relative concentration of short fibers added to an alloy is also a critical parameter to maximize their positive influence on creep resistance. Requena and Degischer (2006) compared the creep behavior of unreinforced and short fiber reinforced

Fig. 12 Minimum creep rate vs. stress for the monolithic alloys and their short fiber composites. Reproduced from Sklenicka, V., Kucharova, K., Kvapilova, M., Svoboda, M., 2015. *Metallic Materials* 53, 221.

Fig. 13 SEM micrograph of a fracture surface from a tensile creep specimen tested at 300°C and 50 MPa stress. Reproduced from Dieringa, H., Huang, Y., Maier, P., Hort, N., Kainer, K.U., 2005. *Materials Science and Engineering: A* 410–411, 85.

AlSi2CuMgNi alloys. Al_2O_3 was also used as the short fiber reinforced material in concentrations of 10 and 15 vol%. During a load changing creep test, that is where the applied load and temperature during testing is varied in specific intervals, the embedding of Al_2O_3 improved the creep rate of AlSi2CuMgNi by more than one order of magnitude (Fig. 14). However, reinforcing the alloy with 15 vol% of Al_2O_3 was more effective than with 20 vol% of Al_2O_3 . This is shown in Fig. 14(a) starting at 1200 h of testing when the applied load is increased to 40 MPa. The AlSi2CuMgNi + 20 vol% of Al_2O_3 begins to go into tertiary creep. This was due to the higher defect density and greater amounts of interface area between matrix and reinforcement with approximately ≤ 1 vol% porosity. Requena and Degischer (2006) showed that the larger amounts of defects in the 20 vol% reinforced alloy accelerated the diffusion controlled creep mechanisms and the larger interface present in the material also increased the diffusivity.

Fig. 14 A comparison of (a) strain vs. time and (b) strain rate vs. time for AlSi12CuMgNi-15 vol% Al₂O₃ and 20 vol% Al₂O₃ for a creep test sequence of 40 MPa/520 h then 30 MPa/315 h then 35 MPa/320 h then 40 MPa/510 h. Note the smaller stationary creep rate shown for the 15 vol% Al₂O₃ than for the 20 vol% Al₂O₃, which reaches the tertiary creep stage when returning to 40 MPa. Long Fiber Reinforced Composites

In comparison to short fiber reinforcement, there is significantly less research published on the influence of long fiber reinforcement on creep properties of light alloys such as Al alloys and in particular, Mg alloys.

Barbera *et al.* (2016) modeled interactions of fatigue and creep damage of an aluminum alloy Al2024 reinforced by Al₂O₃ long fibers which was subjected to cyclic temperature and a constant mechanical load. The different failure mechanisms which occurred such as creep ratchetting, creep-fatigue interaction, and load dwell time originated due to the difference between the fiber and surrounding matrix properties. It was found that the most significant influence to the properties of the composite was the mismatch of the thermal expansion coefficients between the matrix or the alloy and the ceramic Al₂O₃ long fibers. Micro thermal stresses would form and cause matrix micro cracks to be initiated. In order to better understand the complex interactions between matrix and reinforcement an accurate and robust direct simulation technique was utilized based on a linear matching method (LMM) framework. LMM requires a series of linear elastic solutions input parameters which are generated for discrete time points within the creep testing cycle. The values from the LMM were compared to an Abaqus simulation to further improve the understanding of the failure mechanisms in the Al2024 alloy reinforced by Al₂O₃ long fibers (Table 1).

You and Bolt (2002) compared two different matrix materials, a precipitation hardenable CuCrZr alloy and a reduced activation martensitic steel 9CrWCTa (Eurofer) reinforced by long SiC fibers. The matrix materials are used in high temperature applications as structural materials of plasma facing components in fusion reactors. As such, the long fiber reinforced composites were creep tested at 600°C and 200 MPa for Eurofer and 400°C and 200 MPa for CuCrZr. When an axial load is applied to the composites, the long-term creep rupture will occur due to the rupturing of the fibers. If a transverse load is applied, the creep rupture point of the matrix will not be significantly different to that of the long fiber reinforcements. Fig. 15 shows the creep curves of Eurofer and CuCrZr with 10 and 40 vol% SiC long fiber reinforcements under axial loading.

Table 1 Comparison between LMM and step-by-step Abaqus analyses, for different cyclic loading points

Cyclic load point	$\Delta \epsilon_p^L$		$\Delta \epsilon_c$		$\Delta \epsilon_p^{UL}$	
	LMM	Abaqus	LMM	Abaqus	LMM	Abaqus
A ₁	0.0	0.0	2.21×10^{-4}	2.53×10^{-4}	1.80×10^{-4}	2.00×10^{-4}
B ₁	2.26×10^{-3}	2.01×10^{-3}	1.76×10^{-3}	1.74×10^{-3}	3.70×10^{-3}	3.51×10^{-3}
A ₂	0.0	0.0	1.20×10^{-3}	1.25×10^{-3}	1.13×10^{-3}	1.20×10^{-3}
B ₂	5.72×10^{-3}	5.15×10^{-3}	3.22×10^{-3}	3.14×10^{-3}	8.57×10^{-3}	8.15×10^{-3}

Note: $\Delta \epsilon_p^L$ is the plastic strain increment at loading, $\Delta \epsilon_c$ is the creep strain increment, and $\Delta \epsilon_p^{UL}$ is the plastic strain increment at unloading.

Note: Chen, H., Liu, Y., 2016. International Journal of Pressure Vessels and Piping. 139–140, 159.

Fig. 15 Creep curves of the fiber reinforced metal matrix composites plotted for two different fibers and volume fractions. The applied stress was 200 MPa. Two different temperatures were applied to the composites: 600 °C for Eurofer and 400 °C for CuCrZr fiber reinforced metal matrix composites. Reproduced from You, J.H., Bolt, H., 2002. Journal of Nuclear Materials 305, 14.

The influence of the amount of SiC on creep strain is more apparent in Eurofer than with CuCrZr. However, in both base materials, increasing the total concentration of long fiber reinforcement improves the creep strain of the base material (Fig. 15).

Conclusions

In summary, adding ceramic particles (both micro-size and nano-sized) in MMCs is demonstrated to be an effective way to enhance the creep resistance at elevated temperatures. Based on the above, it is concluded that the creep improvement from the reinforcements in the MMCs is either by direct or indirect mechanisms (Chawla and Shen, 2001). Direct strengthening effect means there is effective load transferred from the matrix to the reinforcements. Indirect strengthening effect means the reinforcements do not effectively carry the external load directly, but strengthening the creep resistance by changing the microstructures of the matrix. One potential influence is the generation of dislocations due to the thermal expansion mismatch between the matrix and reinforcements. Another potential effect is microstructural modifications, such as the grain refinement, texture modification during deformation, and transformations of intermetallics, including composition, size, amount, morphology and distribution. These changes could probably relieve the stress concentration, hinder the grain boundary sliding and inhibit the dislocation motions, thus contributing to the creep improvement at elevated temperatures. For micro-sized particles reinforced MMCs, the amount added in the MMCs is always larger than that of nano-sized particles (above 5 vol%) (Labib et al., 2015; Viswanath et al., 2015; Garcés et al., 2007; Hamed et al., 2001). This is resultant due to the particles' relative ease to be broken up and can exhibit relatively uniform distribution in the matrix because of its lower surface to volume ratio than that of nano-sized particles reinforced MMCs. Therefore, it can be fabricated homogeneously with relatively higher volume fraction in the MMCs compared that with nano-sized particles. For nano-sized particles reinforced MMCs, its amount is normally below 5 vol% due to their poor wettability between NPs and matrix (Kumar and Chaudhari, 2014; Ganguly and Mondal, 2018; Katsarou et al., 2016; Daudin et al., 2017; Yang et al., 2019; Tian et al., 2017). It is reported that they can noticeably improve the creep response compared with larger sized counterparts (Haghshenas and Gupta, 2019; Susila et al., 2011). As was similarly concluded for MMC materials in general, for long or short fiber reinforced composites

creep properties are often improved by the transfer of load from the matrix to the fibers. This adds to the support in creep resistance given by grain boundary reinforcement, precipitation hardening, and solid solution strengthening.

However, it is still a challenge to find an effective way to distribute the NPs evenly in the matrix with higher concentrations. Therefore, achieving the balance between the size and distribution of the particles remains as a challenge and further investigations are needed in the future.

Introduction

One of the biggest challenges, engineers face during the design process, is the proper selection of materials (Nturanabo *et al.*, 2019) as some components may demand materials with conflicting properties, such as, light weight with significant strength, brittleness with excellent toughness/stiffness/fatigue resistance. Hence, to overcome these challenges, researchers in the recent past have focused on the development of composites, which gives the flexibility to engineers to select materials with the above mentioned competing properties (Nturanabo *et al.*, 2019; Donnini, 2009; Sharma *et al.*, 2020; Dhanabal *et al.*, 2015; Sujan *et al.*, 2012; Dey and Pandey, 2015; Uthayakumar *et al.*, 2012).

Composites are a mixture of two or more distinct materials, which are bonded chemically at a microscopic scale. One of the constituents of the composite material, which is continuous and available in large quantity is called as the matrix, and the other constituent, which is added to the matrix is called as a reinforcement or a filler. A metal, ceramic or a polymer maybe used as a matrix and if a metal is used then it is called as metal matrix composite (MMC). Likewise, if a polymer or ceramic is used as a matrix then it is known as a polymer matrix composite (PMC) or ceramic matrix composite (CMC), respectively. Furthermore, reinforcements or the fillers are classified based upon their shape, into several categories, such as, particulate, whisker, short/long fiber etc. (Dey and Pandey, 2015). The reinforcement in most of the cases is stronger, harder and stiffer than the matrix. The classification of composites is shown in Fig. 1.

Among the different types of composites, MMCs are the most widely used materials in many demanding applications because of their excellent properties as compared to the parent matrix material. Reinforcing a metal with different fillers has resulted in significant improvements in the mechanical properties such as the tensile strength and hardness along with an increase in their tribological performance in terms of improved wear resistance and low coefficient of friction. MMCs also have a higher working temperature, which makes them attractive for many applications. For example, the composite of aluminum/boron can retain its mechanical properties up to a temperature of 510°C, while the composition of epoxy/boron is limited to 190°C. Moreover, Aluminum/graphite and magnesium/graphite composites have also exhibited higher thermal conductivity.

It is observed from the literature that aluminum (Al) is one of the most commonly used metals in MMCs because of its high strength to weight ratio, which results in superior performance in terms of lower fuel consumption, higher thermal conductivity etc. Furthermore, molten Al has lower viscosity, which allows it to be easily used in the development of MMCs. Nowadays Mg based MMCs have also gained a lot of interest of industries because of their lightweight (two-thirds of aluminum) and good properties (AZoM, 2001; Casati and Vedani, 2014; Lim *et al.*, 2005; Gan *et al.*, 2010). Hence, the excellent mechanical and thermal properties of Al and Mg MMCs make them potential candidates for demanding tribological applications.

The aim of this chapter is to highlight the tribological behavior of light metal matrix composites in general with a special focus on Al and Mg MMCs under different operating and environmental conditions.

Tribological Behavior of MMCs

Generally, metals exhibit higher friction and wear. Therefore, to compensate for the poor tribological behavior of conventional metals, researchers have developed MMCs with improved mechanical, thermal and tribological properties. The most common wear mechanisms in MMCs during sliding are adhesive wear, abrasive wear, fatigue wear, and oxidative (corrosive) wear (Bodunrin *et al.*, 2015; Sambath and Navaneethakrishnan, 2017). Adhesive wear occurs at the interface by combination of applied load and developed shear stress, due to which cold-welding between asperities occur followed by transfer of the softer material to the hard counterpart or the pulled out particles will remain in the contact region and act as wear debris. Abrasive wear occurs when the hard asperities of the rough surface scratch or plow the softer material. For example, in ductile materials, plastic deformation takes place mainly due to the plastic follow of the softer material, while in brittle materials, wear debris entrapment takes place causing brittle fracture. Fatigue wear normally occurs under cyclic loading, resulting in a catastrophic failure, which means a sudden failure with no signs because it starts at the subsurface. Another common wear mechanism in MMCs is the oxidative wear, which takes place during sliding in a corrosive environment.

It is to be noted that, various factors, affect the tribological behavior of MMCs. They are classified into three main categories (Li and Lavernia, 2015; Panwar and Chauhan, 2018):

- (1) Properties of Reinforcement Material (volume fraction, size and shape).
- (2) Operating Conditions (normal load, sliding velocity, and sliding distance).

Fig. 1 Classification of Composite Materials.

(3) Environmental Conditions (temperature, relative humidity).

The effect of each of the above factors will be discussed in detail on the tribological performance of the MMCs in the following sections.

Effect of Reinforcement Volume Fraction on the Tribological Performance of Al/Mg MMCs

The volume fraction of reinforcement in the MMC, plays an important role in the enhancement of hardness of the composite. As per the Archard's wear equation, wear is inversely proportional to hardness. Hence, due to the improvement of hardness, MMCs have shown excellent wear resistance. However, to realize the full potential of these reinforcements their homogeneous dispersion in the matrix become a matter of significance. Hence, different researchers have used different fabrication techniques such as stir casting, powder metallurgy, and ultrasonic stir casting to develop MMCs with uniform dispersion of the reinforcement particles. It has been observed that the volume fraction of the reinforcement particles has shown a direct relationship to the wear resistance of composites. However, higher reinforcement content leads to the problem of agglomerations suggesting that an optimum concentration of reinforcement in the matrix is required beyond which the tribological performance is deteriorated. A reduction in wear rate of Al-MMC with an increasing volume fraction of silicon carbide (SiC) at different loads was observed (Cerit *et al.*, 2008; Choi *et al.*, 2010). Similarly, Mg-MMC reinforced with SiC has also exhibited superior wear resistance under lower loads but under higher loads it has shown higher wear rate. This was attributed to the dominance of melting at the interface due to frictional heating, which results in plastic deformation at the interface. The analysis showed that the useful load range for this composite has to be limited up to 30 N (Mondal and Kumar, 2009). Few researchers found that, beyond 20 vol%, the reinforcement did not contribute significantly to the weight loss of MMCs. Hence, they recommended a limit of 30 vol% volume fraction of the reinforcements (Cerit *et al.*, 2008; Zhang, 2008).

In an another study, wear rate and coefficient of friction of Al-MMC was found to be reduced with an increase in the volume fraction of carbon nanotubes (CNTs). However, when the volume fraction of the CNTs gradually increased beyond 4.5 vol%, the wear rate increased. The increase in wear was attributed to the formation of cracks, voids, and agglomeration of nanoparticles. A similar trend was observed for the coefficient of friction as well (Moghadam *et al.*, 2015). Moreover, no study was conducted to evaluate the tribological performance of Mg-MMCs based on different volume fractions. However, Garcés *et al.* investigated the behavior of magnesium composites reinforced with yttria (Y₂O₃) and found the effect of the volume fraction of Y₂O₃ on young modulus, and hardness, respectively. The study showed a significant increment in young modulus, hardness of the Mg-MMCs as the volume fraction of Y₂O₃ increased (Garces *et al.*, 2006). Based on this, it can be inferred that the developed Mg-MMC may show excellent tribological performance. Table 1, summarizes the studies that have been carried out by different researchers with different reinforcements to develop Al and Mg MMCs and their effect on various properties.

Hybrid metal matrix composites (HMMCs) have also reported lower wear rates as compared to only monotype of reinforcement (Mamgain *et al.*, 2015; Altinkok *et al.*, 2013; Basavarajappa *et al.*, 2006). Al-MMCs were fabricated by reinforcing aluminum with different volume fractions (10%, 15% and 20%) of two different fillers, namely, alumina (Al₂O₃) and SiC. The study reported an increase in wear resistance, impact load, and hardness of the hybrid composite by increasing the volume fraction (Mamgain *et al.*, 2015). Both adhesive as well as abrasive wear mechanisms were observed for the developed composites.

Table 1 Effect of different reinforcements on the properties of the composites

References	Composite	Fabrication process	Operating conditions	Results
(Al-maamari and Iqbal, 2019)	Al 6061/Al ₂ O ₃ and SiC	Stir casting	750°C/200 rpm/1:15 h	– Higher tensile strength. – Higher hardness and impact strength – Higher wear resistance.
(Cerit <i>et al.</i> , 2008)	AA1108/SiC	Powder metallurgy	600°C/30 min/400 MPa	– Higher hardness. – Higher wear resistance.
(Garces <i>et al.</i> , 2006)	Mg/Y ₂ O ₃	Powder metallurgy	400°C/4 h/110 rpm	– Higher modulus of elasticity. – Higher hardness
(Al-maamari and Iqbal, 2019)	Mg/Gr	Powder metallurgy	550°C/60 min/250 kN	– Low wear rate up to the optimum value of 5 wt%.
(Atthisugan <i>et al.</i> , 2017)	Mg/Gr/B ₄ C	Stir casting	800°C/700 rpm	– Low wear rate, high strength, ultimate tensile strength and wear-resistant
(Narayanasamy and Selvakumar, 2017)	Mg/Gr/MoS ₂	Powder metallurgy	530°C/60 min/740 MPa	– MoS ₂ offer better wear behavior than Gr

Table 2 Variation in the effects of volume fraction of Al₂O₃ + SiC on various properties

Composition	Impact load (Nm)	Yield strength (N/mm ²)	UTS (MPa)	Brinell hardness (GPa)
Al 6061 base alloy	5.8	125	184	60
Al 6061 + 10% (Al ₂ O ₃ + SiC)	6.9	145	270	85
Al 6061 + 15% (Al ₂ O ₃ + SiC)	7.9	300	359	105
Al 6061 + 20% (Al ₂ O ₃ + SiC)	8.7	352	415	122

Fig. 2 SEM image showing different wear mechanisms of Al₂O₃ + SiC reinforced Al. Reproduced from Mamgain, R., Manna, A., Mer, K.K.S, Chauhan, A., 2015. Effect of volume fraction (Al₂O₃ and SiC)p on the mechanical properties of Al (6061) hybrid metal matrix composite. International Journal of Scientific & Engineering Research 6 (5), 189–198.

Furthermore, the same phenomenon was observed in other studies as well (Shil *et al.*, 2019; Rathaur *et al.*, 2019). The effects of volume fraction on various properties of Al-MMC are summarized in Table 2 Fig. 2.

Effect of Reinforcement Particle Size on the Tribological Performance of Al/Mg-MMCs

Reinforcement particles size is another important factor, which significantly affects the mechanical and tribological properties such as hardness, wear resistance, and friction coefficient. It is observed that the nano range particles exhibit excellent wear resistance property as compared to micron size particles (Shinda *et al.*, 2020). Tribological studies were carried out on Mg-MMCs reinforced

Table 3 Variation of different particle size on Al, Mg, and hybrid reinforcement

References	Matrix	Fabrication process	Reinforcement details		Operating conditions Load (N); speed (m/s); sliding distance (m)	Results
			Reinforcement	Size; wt%		
Al composites (Goudarzia and Mohammad)	Al5252	PM	SiC	60 μm ; 2.5–10 wt%	15–45; 0.5; 1000	Similar results between base material and reinforced composites at lower loads. Nano composites showed lower wear rate than micro composites at higher loads. COF of nano composites are lower than micro composites.
(Hosseini <i>et al.</i> , 2010)	Al6061	PM	Al_2O_3	30 nm 1 μm 60 μm	20; 0.08; 1000	Lower density and hardness as particle size increase. Higher wear rate as particle size increase.

Fig. 3 Variation of wear rate with varying applied load of Mg matrix. Reproduced from Al-maamari, A.E., Iqbal, A.A., 2019. Wear and mechanical characteristics of Mg-Gr self-lubricating composite fabricated by mechanical alloying. *Journal of Magnesium and Alloys* 7 (2), 283–290.

with SiC_p (Zhang *et al.*, 2008). It was observed that as a result of increasing particle size of SiC_p , wear rate of the Mg-MMC increased. However, some studies have also shown a different pattern in which the wear rate of the composite varied considerably with increasing particle size. The study of aluminum composite reinforced by SiC_p illustrates this exception. It is clearly observed that the wear rate of the composite initially decreased with increasing particle size from 2 to 20 μm but a further increase in the particle size, the wear rate increased significantly. It is concluded that an optimum range of particle size is needed for better tribological properties.

Particle size also has an effect on the coefficient of friction of the composites. Studies were conducted to evaluate the wear rate and coefficient of friction of Al-MMC reinforced by 15 vol% of nano and micro sized Al_2O_3 particles. It was concluded that wear rate and coefficient of friction of the aluminum composite increased with an increase in the particle size of alumina (Jan *et al.*, 2006; Yashpala *et al.*, 2020). Further, the obtained results from the various studies are summarized in Table 3.

Effect of Operating Conditions on the Tribological Performance of Al/Mg-MMCs

It is to be noted that the tribological response of any material is not an intrinsic material property but it is a system's response. Thus, the tribological properties of any material in general are dependent upon the operating and environmental conditions. Therefore, it is necessary to discuss the affect of the operating conditions such as, normal load and sliding speed on the tribological properties of MMCs.

Effect of normal load

It is observed that normal load adversely affects the tribological performance of the MMCs. As the normal load increases, fracture of the reinforcement particles may happen due to an increase in higher contact pressures which further results in higher wear of materials (Al-maamari and Iqbal, 2019). The study of pure magnesium reinforced by different volume fractions (3, 5, 7, 10 vol%) of graphite (Gr) under different normal loads is illustrated in Fig. 3, which was conducted on a pin-on-disk tribometer. It was concluded that as the load increased the wear rate increased for all the compositions. However, the composite of Mg- 5 vol% Gr showed the best tribological performance in terms of lowest wear rate and coefficient of friction. As the volume fraction of graphite exceeded 5 vol%, both, wear rate and friction coefficient increased because of the formation of wear debris. It is also observed that oxidative wear was the predominant wear mechanism at higher loads and adhesive wear was predominant at lower loads (Wilson and Alpas, 1996; Gul and Acilar, 2004). Lim *et al.* (1997) analysed the friction and wear behavior of Al-Cu alloy with graphite particulates. They found a flaky layer of graphite at the counterface due to which, the metal to metal contact reduced, resulting in lower friction coefficient and improved wear resistance. This can be clearly seen in Fig. 4, which exposed that the wear rate increases with increase in applied load for all specimens. In another study, (Lim *et al.*, 2003) reported that magnesium metal matrix composite with interconnected galvanized iron (5 vol%) shows improved mechanical properties such as stiffness and hardness as compared to pure magnesium. They also evaluated the tribological properties of Mg MMCs using a pin-on-disc tribometer at different normal loads ranging from 4 to 30 N and at a sliding speed of 1 m/s. They observed that reinforced composite showed improved wear resistance by a magnitude of 2.7 times that of pure magnesium. Manoj Kumar *et al.* (2005) reinforced magnesium matrix with SiC_p and evaluated the fretting wear of the composites. They reported that abrasive wear was most dominant wear mechanism at the interface, which reduced due to the formation of hydrated magnesium silicate as schematically described in Fig. 5.

Fig. 4 The variation of wear rate with applied load. Reproduced from Lim, S.C., Gupta M., Ng W.B., 1997. Friction and wear characteristics of Al-Cu/C composites synthesized using liquid phase casting process. *Materials and Design* 18 (3), 161–166.

Selvam *et al.* (2014) evaluated the tribological properties of Mg MMC reinforced with ZnO nano particles. They conducted the wear tests at normal loads of 5–10 N, and sliding speeds of 0.6–1.2 m/s for sliding distances of 500, 1000 and 1500 m, respectively. It was observed that wear rate increases with an increment in sliding speed with two different slopes as shown in Fig. 6. Initial slope is observed due to the formation of grooved, scratches and wear-debris and second slope is because of the formation of oxide layer at higher speed. However, a decrement in friction coefficient was observed with increase in sliding distance. Iruthaya Raj *et al.* (2019) added molybdenum nanoparticles in Mg MMC for improvement in tribological properties and mechanical properties. They performed the tribotest on a pin-on-disc tribometer at 1.25 m/s sliding speed and varying applied loads from 5 to 25 N for a sliding distance of 1000 m. A decrease in the wear rate of the composite was observed with an increase in the concentration of molybdenum at all loads as shown in Fig. 7.

Uthayakumar *et al.* (2012) developed a hybrid metal matrix of Al reinforced by 5 vol% of SiC and 5 vol% of B₄C and evaluated its tribological properties using a pin-on-disc test. Wear and coefficient of friction were evaluated under varying loads between 20 and 100 N at different sliding velocities. The investigation showed high friction coefficient for unreinforced aluminum, while a low coefficient of friction for the reinforced matrix with a critical load point of 60 N. The reduction in the friction coefficient was attributed to the generation of boron oxide layer at the contact zone due to the frictional heat. Increasing the load beyond the critical point caused the coefficient of friction to increase due to the rupture of the oxide layer. Another investigation was conducted on a composite of Al reinforced by B₄C, which exhibited a critical load point of 65 N. It is concluded that the ceramic particles, which are embedded in the Al matrix, reduced the plastic deformation. As it is known that, Al is environmentally reactant and forms an oxide layer during sliding. The formed oxide layer reduces the contact between surfaces, and the pull out of these particles is very low at lower loads. However, once the load increases beyond a critical point, the pull out increases due to the tearing of the oxide layer due to which large amount of wear debris are generated. The large generation of debris indicates severe plastic deformation. Same effect was observed in a study on Al reinforced by SiC (Alpas and Zhang, 1992; Natarajan *et al.*, 2006). Table 4 gives a summarized view of the effect of load on the tribological properties of MMCs for an easy understanding.

Effect of sliding speed

Sliding speed is another important factor, which affects the tribological behavior of MMCs. From the previous studies it is observed that the sliding speed has a direct proportionality with wear rate. In other words, increasing the sliding velocity increases the wear rate. The effect of sliding speed does not only stop on increasing wear rate, but it also increases the temperature at the interface between the surfaces, resulting in the softening of the matrix, increased rate of oxidation, and a reduction in material flow stress. As a result, the sliding velocity might have different effects on the MMCs with different materials (Natarajan *et al.*, 2006). Further, the effect of sliding speed on wear rate of aluminum reinforced by different weight percentages (2.5, 5 and 7.5) of MoS₂ and 10 wt% of B₄C have illustrated by Monikandan *et al.* (2016). The addition of MoS₂ and B₄C enhanced the hardness and fracture toughness of the composite. The addition of MoS₂ aided in the formation of a lubricated layer that reduces the wear rate and friction coefficient. However, when the sliding velocity increased beyond 2 m/s, wear rate and coefficient of friction gradually increased due to a rise in temperature resulting in the evaporation of the lubricated layer leading in metal-to-metal contact (Monikandan *et al.*, 2016).

Weia *et al.* (2013) investigated the tribological properties of Mg MMC reinforced with SiC and MWCNTs at different sliding velocities. It was observed that the addition of SiC and MWCNTs tends to increase the specific wear rate at a low sliding velocity of 1.5 m/s. while for higher velocities, specific wear rate decreased gradually up to 3.5 m/s. A combination of abrasion and oxidation wear mechanisms were found to be responsible for higher wear rates a sliding velocity below 1.5 m/s. Once the velocity goes beyond 1.5 m/s, the wear at the grooves, which were formed at low speed are transformed to scratches followed by plastic deformation causing a drop of the wear rate. The drop is related to the increase in flash temperature due to the increase in the

Fig. 5 Schematic representations of wear mechanisms during tribotest. Reproduced from Manoj Kumar, B.V., Basu, B., Murthy, V.S.R., Gupta, M., 2005. The role of tribochemistry on fretting wear of Mg-SiC particulate composites. Composites – Part A, 36, 13–23.

sliding velocity causing softening of the mating surfaces in which the lowest wear rate was recorded at 3.5 m/s. Another investigation shows similar behavior in which at higher speeds, wear is transformed from cutting to plowing where the removed materials are displaced. As a result of that, the use of SiC and MWCNTs appears to be more beneficial when used at higher speeds in which wear rate decreases. It was observed that the removal rate of the oxide layer rate is higher during sliding as compared to the rate of formation (Weia *et al.*, 2013; Lim *et al.*, 2005). Shanthi *et al.* (2010) reinforced AZ31B magnesium alloy matrix with aluminum oxide with/without calcium and investigated its tribological performance under different conditions. They observed that the composite showed abrasive wear at lower speeds and adhesive wear at higher speeds. At higher speeds, the thermal softening played a very important role in the reduction of friction coefficient and wear resistance (up to 30%), which can be clearly

observed from Fig. 8. (Srinivasan *et al.*, 2012) developed AZ31B and nano composites (AZ31B- Al_2O_3 -Ca) using hybrid-casting process followed by hot extrusion. Pin-on-disc wear tests were conducted for a sliding distance of 2000 m at a normal load of 10 N at different sliding speeds, ranging from 0.6 to 1.2 m/s at room temperature. They also observed similar behavior that the wear decreases with an increase in sliding speed and observed plowing groove, adhesion and oxidation to be dominant wear mechanisms followed by thermal softening at higher speeds. Table 5 presents a summarized view of the different studies showing the effect of sliding speed on the tribological properties of Al and Mg MMCs.

Effect of temperature

Temperature is another important factor that affects the wear behavior of the composites, which results from the increase in the sliding velocity, and load as discussed in earlier sections. Poor strength and bonding at high temperatures are the main problems that sidelined magnesium and aluminum for demanding applications, and the effective approach to overcome this is adding reinforcement with the matrix to enhance its mechanical properties at higher temperatures. Some studies reported that the addition of reinforcement is beneficial only at lower loads and temperatures (Labib *et al.*, 2016). A study was conducted on Al6061 and Al A356 reinforced by SiC, Al_2O_3 , and graphite, respectively. The effect of ceramics and graphite were tested under specified operating conditions of low load (11.55 N), and low sliding velocity (0.1 m/s). Effect of reinforcements is shown in Table 6. The transition temperature from mild to severe wear differs from one to another reinforcement. The ability for the reinforcement to

withstand higher temperatures before softening was attributed to the layer formation, and dislocations of wear debris. The ability of graphite to sustain higher temperature is due to high friability. However, the addition of graphite reduces strength (Wilson and Alpas, 1996).

These variations in the transition temperatures depend on the type of composites. Critical temperatures have existed, which affect the wear rate and friction coefficient behavior adversely. For instance, using molybdenum disulfide, which exhibits a good self-lubricating property, shows lower wear rate and coefficient of friction. However, once temperature goes beyond 400°C, the solid lubricant oxidizes, and it won't be considered as a good lubricant. Furthermore, the wear rate and friction coefficient of aged aluminum reinforced with SiC under varying temperatures ranging between 20 and 250°C, at a normal load of 20 N, a sliding velocity of 0.5 m/s, and total sliding distance of 2.5 km was studied by Khorshid *et al.* (2013). It was shown that the reinforced matrix exhibited higher wear rate and coefficient of friction than unreinforced aluminum in the temperature range of 25–125°C. However, with a further increase in temperature the wear rate and friction coefficient for the unreinforced aluminum increased sharply, whereas, for the reinforced aluminum it kept decreasing until a temperature of 200°C. After 200°C, even the reinforced aluminum showed a sharp increase in the wear rate and friction coefficient. This was attributed to the softening of the interface between the matrix and the reinforcement particles resulting in the easy pull out of the material (Zhang and Alpas, 1997).

Mg-MMCs reinforced with SiC particles (5, 10, 15 vol%) were evaluated at different temperatures in the range of 25–200°C at a normal load ranging from 5 to 60 N and at a constant sliding velocity of 0.4 m/s. It was observed that at lower temperatures, reinforced and unreinforced composites exhibited a similar behavior in terms of wear rate under normal loads between 5 and 20 N. However, under higher loads, as the volume fraction increased, the reinforced composites showed a lower wear rate as compared to the unreinforced magnesium. The lower wear rate of reinforced composites over pure magnesium was attributed to the higher hardness and strength, which results in more matrix deformation resistance (Labib *et al.*, 2016).

Furthermore, it is shown that as temperature increases, the material load transition decreases. However, as normal load increases, wear transition rate occur from mild to severe wear at each wear temperature. For instant, the transition load decreases from 60 N to 40 N when the temperature changes from 100 to 150°C. When the temperature changes from 150 to 200°C, there was no noticeable change in load transition. The reason for that was attributed to the fact that the temperature going beyond the critical temperature of that composite (Wilson and Alpas, 1996). Below the transition load and temperature, oxidation wear was the main mechanism, while beyond the transition temperature, abrasion and adhesion were predominant. For instant, transition from mild to severe wear occurs at lower loads by increasing temperature from 100 to 150°C. The investigation also showed that as the volume fraction of reinforcements increased, the transition wear decreased (Labib *et al.*, 2016).

Conclusions

It is observed that various factors such as volume fraction of reinforcements, particle size of reinforcement, interface temperature, normal load and sliding speed affect the tribological and mechanical behavior of MMCs. The following specific observations can be drawn from the extensive review presented above.

- (1) The volume fraction of reinforcement has a direct relationship with wear resistance. The particles that are distributed on the surface of the matrix protect the surface from abrasive wear during sliding. However, as the volume fraction increases, wear rate and coefficient of friction decreases under normal conditions; Moreover, under high loads, particles get softened, which results in the increase of wear resistance. The addition of reinforcement is limited to a certain volume fraction of 30 vol%

Table 5 Summary of the effect of operating conditions on the tribological performance of Al and Mg MMCs

Reference	Matrix	Process	Reinforcement	Operating Conditions	Results
(Radhika <i>et al.</i> , 2011)	Al	S.C	Al ₂ O ₃ & Gr	(20,30, and 40) N; (1.5–3.5) m/s; 2100 m	– Wear rate and FC decrease as sliding velocity increase – Composite showing minimum temperature rise than Mg.
(Monikandan <i>et al.</i> , 2016)	AA 6061	S.C	B ₄ C & MoS ₂	20 N; 1000 m	– MoS ₂ formation reduces the wear rate of HMMC up to sliding speed of 2 m/s, then wear rate is going to increase. – Hardness and fracture toughness decreased with increase in MoS ₂
(Liu <i>et al.</i> , 2010)	Al	P.M	AlN	(5–35) N; (0.01–0.08) m/s; 30 min	As sliding velocity increase, Wear rate decreases.
(Lim <i>et al.</i> , 2005)	Mg	DMD	Al ₂ O ₃ (0.22–1.11 vol%)	10 N; (1–10) m/s; 600 m	– Exhibited improved wear resistance – Reinforcement improved the hardness – Abrasion and oxidation are the most predominant wear mechanisms at low speeds, while adhesion at higher speeds.
(Kaviti <i>et al.</i> , 2018)	Mg	P.M	BN (0.5–2.5 wt%)	5–10 N, 0.6–1.2 m/s	0.5 wt% BN reinforced composite showed excellent friction coefficient and wear resistance property as compared to other concentrations.

beyond which the wear rate and friction coefficient become almost independent of the volume fraction. Furthermore, hybrid reinforcement composites exhibit better mechanical and tribological properties.

- (2) Particle size has a predominant effect on the behavior of metal matrix composites. Studies show that in general, as the particle size is reduced, the composites exhibit higher mechanical properties. However, several studies have also showed some unclear results of micron-sized particles. Some studies showed an improved tribological behavior while other showed the opposite. On the other hand, the nano particles have shown improved wear resistance, hardness, and friction coefficient once agglomeration is controlled.
- (3) Normal load is one of the operating conditions that affect the tribological behavior of the composites. As the load increases, both wear rate and friction coefficient are also increased due to the increase in the real area of contact. There is a critical load for each composite in which wear is transferred from mild to severe wear drastically. At lower loads, adhesive wear is predominant, while at higher loads, oxidation wear was found to be a predominant wear mechanism. Once critical load is exceeded, oxide layer breaks resulting in high wear rate.
- (4) Sliding speed is another important parameter that influences the tribological behavior of MMCs. It was observed that it has a linear relationship with wear rate. At lower speeds, the predominant wear mechanism at the interface was found to be abrasion but at higher speeds adhesion and oxidation was found to be a dominant wear mechanism due to thermal softening.
- (5) Elevated temperatures that result mostly due to an increase in the normal load and sliding velocity have a significant effect on the tribological behavior of MMCs. One of the main problems occurring due to the increasing temperature is poor bonding. A better choice of reinforcement may result in improved thermal stability of the composite. However, in general, a composite showed higher thermal stability as compared to the unreinforced metals.

Aluminum Based Nanocomposites

The growing environmental concerns in industries and the end users has led to a surge in the use of lightweight materials for various engineering applications (Kumar *et al.*, 2018; Baba *et al.*, 2019). Further, the favorable properties associated with aluminum such as easy castability, better thermal conductivity and ease of machining makes aluminum a good candidate material for a variety of engineering applications particularly for automotive and aerospace applications (Suresh and Moorthi, 2013). Materials used for modern engineering components, particularly in machines, apart from possessing better mechanical properties should exhibit better tribological properties as friction and wear are the main causes of failure in engineering components that undergo relative mechanical motion (Haq and Anand, 2018). Aluminum, in its pure form offers very little structural advantage and also loses its performance capability at elevated temperatures. Apart from poor mechanical properties, aluminum in its pure form, due to its soft nature, also has poor tribological properties. A variety of measures have been adopted previously to address these issues such as: (1) heat treatment of the cast components, (2) alloying aluminum by various agents to form better strength alloys and (3) development of Aluminum Metal Matrix Composites (AMMCs) by reinforcing aluminum by various micro-sized particles (such as SiC, Al₂O₃, TiB₂, Si₃N₄, TiC, B₄C, etc.) (Bodunrin *et al.*, 2015; Omrani *et al.*, 2015). Making of composites provided superior properties than mere heat treatment alone. However, depending on the nature of the reinforcement, composites have some drawbacks, such as poor toughness and ductility, excessive tool wear during machining operation, higher wear rate of counterface materials in tribological systems. It is well known that the reinforcement of aluminum with various ceramic reinforcements leads to increased porosity content, particularly at the matrix-reinforcement interface. Fracture of components is related to porosity content as porosity act as potential sites for crack nucleation. Porosity formation also depends on the reinforcement particle size as it is widely accepted that larger sized particles degrade the inter-particle cohesion. In addition to the aforementioned factors, particle clustering also contributes towards ductility reduction and eventually lowering the fracture toughness. Casting and Powder Metallurgy (PM) are the widely adopted methodologies for development of AMMCs, however due to technical difficulties associated with PM route to produce large sized parts, casting is the more common method. Further, due to the lower melting point of aluminum, casting is more cost-effective route for development of AMMCs.

With the recent developments in the field of nanotechnology, aluminum nanocomposites (NCs) have gained impetus as a material option for various engineering applications, wherein various nano-sized reinforcement (size < 100 nm) are added to aluminum and its alloys. Nanocomposites, if developed through an appropriate processing route can overcome the aforementioned limitations of AMMCs with micron-sized reinforcements. As reported by various researchers, NCs offer higher strength, improved hardness, better ductility, improved fracture toughness and better tribological behavior even at lower reinforcement content as compared to conventional composites (Jayalakshmi and Singh, 2015). Properties of aluminum nanocomposites are enhanced primarily because of smaller size of reinforcements, as large sized particles cause inhomogeneity in matrix. Owing to inhomogeneity, localized stress concentration is experienced near particles, when material is subjected to external loads, thereby causing the material to fail even at lower applied loads (Gnjidić *et al.*, 2001; Lloyd, 1991) and brittleness in the material.

Types of Aluminum Nanocomposites

Aluminum nanocomposites are being proposed for variety of applications because of their better properties in comparison to base matrices. Nanomaterials that are added as reinforcement to aluminum and its alloys in the form of nanoparticles, nanotubes, nano flakes and nanofibers. Fig. 1 shows the classification of different types of nanomaterials used as reinforcement. Graphene based nanocomposites have gained much focus in recent years due to their good strength and elastic modulus. Graphene has high strength of 130 GPa and is the basic building block for CNT's (Carbon nanotubes) and fullerenes (Prashantha Kumar and Xavier, 2014; Jang and Zhamu, 2008).

Studies on use of graphene as a reinforcement have shown better mechanical and tribological properties of the composites. Properties of graphene-based nanocomposites are also dependent upon their volume fraction (or weight fraction). Addition of 0.5–2 vol% of graphene in aluminum composite improved compression strength from 330% to 586% in comparison to that of the base matrix. High tensile strength and good elastic modulus of graphene contributes strongly in enhancing the strength of matrix (Li *et al.*, 2018).

Synthesis of graphene-based nanocomposites remains a challenge due to their poor dispersion and agglomeration (Prashantha Kumar and Xavier, 2017). Better dispersion results in improved ductility of aluminum alloys. Poorly dispersed nanoparticles

Fig. 1 Classification of nanomaterials used as reinforcement in aluminum nanocomposites.

becomes a cause of agglomeration at interface of grain boundaries, which further leads to development of cracks upon elongation (Boostani *et al.*, 2015a). Boostani *et al.* (2015b) used graphene sheets and SiC as reinforcements in aluminum powder prepared via powder metallurgy route. Their results were compared with SiC in aluminum matrix and graphene encapsulated SiC in aluminum matrix. It was observed that graphene encapsulated SiC resulted in improved yield strength and ultimate tensile strength by 81% and 60%, respectively. This was due to the less agglomeration of SiC particles. Hence, it was observed that graphene encapsulation lead to improvement in dispersion which further improved the mechanical properties.

Some researchers have opined that agglomeration of nanoparticles can be prevented by ball milling aluminum powder with graphene nanoparticles and casting the matrix ultrasonically in semisolid state (Kai *et al.*, 2013; Yang *et al.*, 2004). Results have shown substantial improvements in mechanical properties. However, complete viability of the method can only be established only if other properties such as thermal conductivity and ability of graphene sheets to prevent agglomeration are investigated (Boostani *et al.*, 2015a).

Addition of CNT's and MWCNT's have also resulted in improved strength of nanocomposites. Further, their effect on tribological properties is also substantial, but the issue of uniform distribution of nanotubes needs to be addressed. Wettability issues and lower contact area also affects the properties of nanocomposites having nanotubes (Odom *et al.*, 1998). In the recent past, various studies have been undertaken to address these issues, wherein it was observed that wet ball mixing can be used to improve the dispersion of CNT in aluminum matrix (Laha *et al.*, 2007). Further, ultra-sonication of CNT followed by ball milling with aluminum showed improved dispersion that resulted in refinement of grains (Laha *et al.*, 2007).

Hanizam *et al.* (2019) carried out a study with MCWNT in A-356 aluminum alloy using stir casting process. Their results were obtained for different weight percentage of MCWNT (0.5 wt%, 1 wt%) and magnesium (0.25 wt%, 0.5 wt%) corresponding to varying stirring times. A corresponding improvement of 76.3% and 108.4% in the hardness and UTS was reported for 0.5 wt% MCWNT and 0.5 wt% Mg in comparison to the base matrix. It was also observed that the mechanical properties of aluminum composites containing MCWNT can be enhanced by thixoforming and heat treatment.

Brief Overview of Processing Routes

Nanocomposites, a well-recognized name in the domain of composites has given a good competition to microcomposites. Apart from type of reinforcements, processing routes also influence the properties of NCs. A common distinction amongst various processes for the fabrication of metal matrix nanocomposites can be made based upon the state of the matrix during fabrication. The state can be either molten, semi-solid, or solid. This section briefly presents various processing routes adopted in the development of NCs.

Liquid state processes

Liquid state processes for the development of metal matrix nanocomposites (MMNCs) are the most preferred route due to their cost-effectiveness, simplicity, and potential for producing near-net-shape components (Dehghan Hamedan and Shahmiri, 2012; Mazahery *et al.*, 2009; Sajjadi *et al.*, 2011). Some of the processes related to the liquid state of materials are casting, melt deposition, infiltration, and ultrasonic assisted casting.

Stir casting

Stir casting is the liquid state process which has been widely used for development of MMNCs, due to its economy and simplicity. This method is generally used with a large volume of metal (Clyne and Withers, 1995; Hashim *et al.*, 1999; Surappa, 2003). In this method, mechanical stirring is carried out to mix a dispersed phase in a metal matrix (in the molten form). Efficient mixing is achieved due to the high viscosity of semi-solid matrix material. Stirring carried out in furnace is the critical component of this technique. Molten material produced with reinforced nanoparticles is solidified by die/sand/permanent mold casting. Oxides of magnesium (MgO), aluminum (Al₂O₃), zirconia (ZrO₂) and silicon carbide (SiC) nanoparticles as well as carbon nanotubes (CNTs) have been associated with magnesium and aluminum matrices using stir casting method (Dehghan Hamedan and

Shahmiri, 2012; Hemanth, 2009; Li *et al.*, 2010; Sajjadi *et al.*, 2011; Suresh *et al.*, 2011; Yar *et al.*, 2009). In order to deal with clustering and wetting issues, nanoparticles are ball milled and pre-dispersed on metal powder surface. These powders are then mixed with molten metal through stirring. Nanocomposite synthesis reinforced with CNTs, Al_2O_3 , and SiC have been carried out using this technique (Dehghan Hamedan and Shahmiri, 2012; Karbalaee Akbari *et al.*, 2013b; Mazahery *et al.*, 2009; Mazahery and Shabani, 2012a,b; So *et al.*, 2013; Su *et al.*, 2012a,b).

Ultrasonic assisted casting

This type of casting is considered to be more effective in solving issues of particle clusters that usually result in agglomeration and poor wettability (Cao *et al.*, 2008b; Donthamsetty, 2009). In this method, the melt is treated with ultrasonic waves with a frequency range of 18–20 kHz. This treatment is carried out simultaneously or post to reinforcement phase addition. This technique has been extensively researched for development of Al based nanocomposites by adding reinforcements such as AlN, CNTs, SiC, Al_2O_3 , and B_4C , CNTs, and AlN (Cao *et al.*, 2008a,c; Choi *et al.*, 2012; Donthamsetty, 2009; Lan *et al.*, 2004; Mula *et al.*, 2009; Puga *et al.*, 2013; Yang *et al.*, 2004).

Infiltration process

In this process, a porous preform is injected with pressurized liquid metal. Composites with micro-sized reinforcements have been developed by this technique e.g., SiC particles, AlN, TiC, Al_4C_3 glass fiber, etc. (Balch *et al.*, 1996; Fukunaga and Goda, 1984; Lai and Chung, 1994a,b; Muscat and Drew, 1993; Rohatgi *et al.*, 1998). Preform is prepared from slurry comprising of reinforcement, binder, a liquid carrier. Subsequently, the preform is subjected to drying and heat treatment to retain dimensional stability during the pressure-assisted molten metal infiltration.

Disintegrated melt deposition

This process was employed to carry out homogeneous mixing of nano-reinforcements in aluminum and magnesium alloys. This technique was developed for preparation of discontinuously reinforced MMCs of near-net-shape (Tham *et al.*, 1999) and involves both, casting and spray processes. In this process, ceramic particles are incorporated into molten matrix during stirring of the mix. Composite slurry thus formed is further disintegrated with using inert gas jets at 750°C and is deposited on a metallic substrate. Ingots thus produced are subjected to secondary processes such as extrusion. It is a bottom pouring process and hence (1) eliminates the need for separate melting and pouring units (2) removes oxides and slag/dross with least metal wastage and (3) eliminates retention/settling of nano-reinforcements in crucible (Ceschini *et al.*, 2016).

High pressure die casting

Besides, semi-solid and stir casting methods, high pressure die casting (HPDC) has also been used for the development of MMNCs. As compared to low pressure die casting, this process enables the development of more components with detailed dimensions. In this method, metal in the molten state is forcibly fed into a die cavity. Solidification rate and filling speeds in this process are very high. Due to this, HPDC method is categorized by fast cycle times ranging from few seconds to several minutes, subjected to the size and thickness of the casting. The process also causes entrapment of gas due to high turbulence of metal in die cavity (Long *et al.*, 2012; Wang *et al.*, 2011).

Solid state routes

Synthesis of many nanocomposites has been made by solid-state process of powder metallurgy (PM) technique. Wettability issues between matrix and reinforcement are of no/less concern with this process (Suryanarayana and Al-Aqeeli, 2013). PM process also produces near-net-shape parts. Major advantage of this method is the possibility to form numerous combinations of matrix and reinforcements, and higher volume fraction of reinforcement can be easily incorporated. Automotive industry is using PM process on a large scale for manufacturing of small-sized parts (Cintas *et al.*, 2005). High price of powders and increased porosities are some of the drawbacks of PM process which further require certain secondary processing such as forging, rolling, extrusion, etc., (Ye *et al.*, 2005). Basic steps involved in PM process are (1) mixing of powders, (2) compaction of powders and (3) sintering of powders.

Mixing of powders can be carried out by different methods such as mortar pestle, cone mixing, ball mixing, etc. Compaction of green compacts is carried out by processes such as hot isostatic pressing (HIP), hot extrusion and vacuum hot isostatic pressing (Liu *et al.*, 1994). To consolidate powders, other process such as equal channel angular pressing (ECAP), have been also used (Bera *et al.*, 2013). Similarly, there are different sintering arrangements e.g., conventional sintering in a resistance furnace, induction sintering, microwave sintering, bidirectional hybrid microwave sintering, etc.

Semi-solid state processes

This process is based on partial solid mixtures commonly known as slurries. These mixtures are shaped with solid fractions in the form of small globular grains ranging from 20% to 60%. Commonly, these processes are associated with low porosity, low shrinkage, low processing temperature and non-turbulence. Semi-solid methods can be classified into processes, mainly thixo-processes and rheo-processes.

Thixo-processing

In this process, a solid feedstock is brought into a partly melted state. The base matrix is prepared by partially solidifying liquid melt in controlled atmosphere, and this leads to crystal generation in the slurry. Preparation of feedstock may be done in different ways, e.g., stirring during solidification, ultrasonic treatment and continuous casting by employing magneto-hydrodynamic stirring (Fan, 2002; Dobatkin and Eskin, 1996; Liu *et al.*, 1998). The material in semi-solid state is then injected into dies. Since slurry can be obtained in different ways, this process is considered to be optimized and tailorable for development of MMNCs (Kiuchi and Kopp, 2002).

Rheo-processing

In this process, there is no requirement for a special feedstock. During casting process, the slurry in semi-solid state is prepared from liquid state by cooling process. This process is relatively easy and can be implemented in foundry and the requirement is of standard equipment for handling, treatment, melting, transportation, and degassing. Slurry making is generally the key point in differentiating various approaches. Production of a robust slurry on-demand requires great efforts, and thus different processes evolve. It is worth mentioning here a new technique called New Rheo Casting process (NRC) amongst various rheo-processes techniques. NRC depends on the cooling gradient to create the initial slurry (Yasunori *et al.*, 1996). A large number of crystals are formed when molten metal is poured at low superheat into a holding cup. Thereafter, for the previously set time, the slurry held in the cup, and this leads to growth of crystals. Thereafter, spheroidization of crystals occurs even without additional stirring.

Additive Manufactured Aluminum Nanocomposites

Additive Manufacturing (AM) has evolved as a disruptive technology for development of engineering parts in general, and composites in particular, owing to its (1) ability to handle complex geometries, (2) lower cost even for smaller production volumes, (3) less human interventions, (4) increased product customization and (5) little or no post processing (Chadha *et al.*, 2019). AM technology involves layer-by-layer building up of a part, directly from a CAD geometry, thereby can handle complex geometrical intricacies and results in very less wastage of material (Abdulhameed *et al.*, 2019). Further, limitations encountered in conventional manufacturing such as non-uniform distribution of reinforcing agents, poor wettability of reinforcements inside the molten melt, clustering of reinforcement particles etc. are overcome by the use of AM technology (Gu *et al.*, 2014). A variety of methods of additive manufacturing have been developed having the ability to fabricate parts for a wide range of materials, to print large sized parts having desired mechanical properties with minimum defects. Fig. 2 shows the various AM technologies available for fabricating different materials (Ngo *et al.*, 2018).

With regard to development of aluminum composites, as reported by various researchers, Selective Laser Melting (SLM) and Selective Laser Sintering (SLS) are the commonly used technologies (Ngo *et al.*, 2018). In this direction, Gu and Yuan reported that SLM is not only capable of producing high performance nanocomposites with enhanced properties, but also can generate unique microstructure (Gu and Yuan, 2015). Ma *et al.* (2015) in their work on the development of aluminum based nanocomposites (AlSi10Mg and TiN) prepared by mechanical alloying and SLM have reported that milling prior to SLM plays a key role in evolution of microstructure and uniform distribution of particles in Al-matrix. Further, Vickers' hardness of the developed hybrid composites increased and coefficient of friction (COF) decreased, besides improving the density of composites. In a recent work by Safavi *et al.* (2019), the authors have opined that in comparison to conventional AM technologies, Ultrasonic Additive Manufacturing (UAM) offers advantages because of lower operating temperatures resulting in components with tailored coefficient of thermal expansion (CTE) and less intermetallic compounds. In a related study (Gao *et al.*, 2020) developed TiN/AlSi10Mg nanocomposites by employing ultrasonic vibration technique together with SLM. The authors have reported that TiN nanoparticles play a vital role in grain refinement and 4 wt% TiN nanocomposites exhibited better tensile strength, ductility and microhardness in comparison to conventional composites. The authors attributed this behavior to the improvement in density, grain refinement and resistance offered by uniformly distributed TiN nanoparticles to the dislocation.

In a study by Hu *et al.* (2018), the authors reinforced aluminum by graphene via SLM and reported an 75% improvement in hardness. Similarly, Zhou *et al.* (2019) prepared an aluminum alloy and graphene oxide composite via in-situ method and reported better accuracy. Lin *et al.* (2019) developed aluminum nanocomposites by Laser Additive Manufacturing and reported improvements in yield strength, plasticity and thermal stability as compared to unreinforced aluminum. The improved density, uniformly dispersed nanoparticles, better bonding between Al matrix and nanoparticles and Al matrix, refined grain structure contributes to this behavior.

While AM processed aluminum nanocomposites offer better properties in comparison to conventional manufactured parts, however apart from economic constraints these parts suffer some drawbacks such as:

- (1) Micro-cracking during SLM, due to fast cooling rates (Aboulkhair *et al.*, 2014).
- (2) Porosity due to fast scan speed and formation of oxides (Kaufmann *et al.*, 2016).
- (3) Surface defects and laser spatter (Yang *et al.*, 2019).
- (4) Distortion of shape due to thermal stresses (Buchbinder *et al.*, 2014).

Nevertheless, these limitations can be overcome by selecting the right nanoparticle size and shape and fabricating the parts at optimal process parameters.

Fig. 2 Different AM Technologies with compatible materials and benefits.

Aluminum Based Nanocomposites: Mechanical Behavior

Composites are developed taking into consideration the desired properties related to specific applications wherein improvement in the mechanical properties in nano reinforced composites than micro reinforced composites. A noteworthy enhancement in yield strength (YS) and ultimate tensile strength (UTS) with the reinforcement of nanoparticles has been reported by researchers (Fig. 3, Ezatpour *et al.*, 2014; Oh *et al.*, 2012; Fig. 4; Sajjadi *et al.*, 2012, 2011; Tahamtan *et al.*, 2013; Yang and Li, 2007). Substantial enhancement in the Young's modulus have also been reported (Karbalaee Akbari *et al.*, 2013a,b; So *et al.*, 2013).

In nanocomposites, improvement in YS values as compared to monolithic aluminum matrix is mainly attributed to grain refinement, improved dislocation density (Sanaty-Zadeh, 2012; Zhang and Chen, 2008). However, improvement in tensile strength is attributed to work hardening mechanism triggered by nanoparticles (Mazahery *et al.*, 2009). Decrease in mechanical properties has been observed by researchers beyond a critical volume/weight reinforcement (Sajjadi *et al.*, 2012; Ezatpour *et al.*, 2014; Mazahery *et al.*, 2009). The decrease is mainly due to the increasing content of nanoparticle clusters and a relatively higher micro-porosity (Ezatpour *et al.*, 2014).

Carbon nanotubes due to their properties have been used as reinforcement by several researchers. Aluminum matrix (Al1060) with carbon nanotubes as reinforcements were developed by friction stir processing (Zhang *et al.*, 2019). Influence of energy input on microstructure and mechanical properties of the composites was investigated. It was observed that the coarsening of grains took place with an increase in energy, and the microstructure revealed uniform incorporation of nanotubes. Higher energy inputs resulted in the 53.8% and 31.2% increase in tensile strength and ductility, respectively as compared to the unreinforced alloy (Fig. 5). Grain refinement, transfer of load, and Orowan looping were the main strengthening mechanisms (Zhang *et al.*, 2019). AlSi10Mg alloys were reinforced with carbon nanotubes (CNTs) using a selective laser melting (SLM) technique (Gu *et al.*, 2019). It was identified that densification behavior of SLM based composites depends upon scan speed and laser power. Their findings have revealed that a fully dense nanocomposite was developed with 350 W laser power and at 2.0 m/s scan speed. These

Fig. 4 Tensile stress-strain curves showing enhancement in strength properties of A356 -Al₂O₃ nanocomposite. Reproduced from Sajjadi, S.A., Ezatpour, H.R., Torabi Parizi, M., 2012. Comparison of microstructure and mechanical properties of A356 aluminum alloy/Al₂O₃ composites fabricated by stir and compo-casting processes. *Mater. Des.* 34, 106–111. Available at: <https://doi.org/10.1016/j.matdes.2011.07.037>, Used with permission.

composites have shown increased hardness, tensile strength, and elongation of 154.12 HV, 0.2, 420.8 MPa, and 8.87% (Fig. 6), respectively (Gu *et al.*, 2019). Multi-walled carbon nanotubes (MWCNTs) in weight percentages of 1, 2, and 5 were reinforced in pure Al matrix using powder metallurgy route (Ostovan *et al.*, 2015). The mixture was ball milled followed by compaction and sintering. Ball milling was carried out separately for 0.5, 2, 5, 8, and 12 h. Influence of milling time along with the proportion of MWCNTs on the mechanical properties was reported by the authors. Their findings have revealed that ball milling time influences mechanical properties, and an increase of 60%, 60% and 35% was observed in nano hardness, microhardness and yield strength, respectively (Ostovan *et al.*, 2015). Researchers have attempted to develop carbides at low temperatures, and for this purpose, amorphized graphite was added to the composites (Khorasani *et al.*, 2015). With this technique, wettability issue was resolved. Aluminum was reinforced with amorphous carbon nanotubes (CNTs) using powder metallurgy. The ratio of graphite to CNT used was 1:6. The main objective of this study was to increase the wettability and microhardness of the developed composites. Results showed improvement in wettability and increase in microhardness. This was mainly attributed to the addition of amorphized graphite to CNTs. Improvement in mechanical properties was due to the formation of aluminum carbide (Al₄C₃) which resulted in increased adhesion between CNTs and the aluminum matrix (Khorasani *et al.*, 2015).

Graphene was coated with nano-Al using an organic aluminum reduction method (Zhao *et al.*, 2019). The coated graphene was then mixed with AlSi10Mg alloy by ball milling and nanocomposites were developed using SLM. Mechanical properties and wear behavior of the composites was investigated. Al coating improved the wettability of graphene with Al and resulted in high nucleation rates, thus refining the grains. This increased tensile strength, hardness, and wear resistance (Zhao *et al.*, 2019). Graphene has also been associated as reinforcement in aluminum base matrix using 3D printing. Pure aluminum powder and multi-layered graphene sheets were subjected to ball milling followed by 3D printing using SLM technique (Hu *et al.*, 2018).

Fig. 6 Ultimate tensile strength (UTS) and elongation of Selective Laser Melting (SLM) fabricated Al-CNT composites with varying scan speed, compared with unreinforced AlSi10Mg specimen fabricated at scan speed of 2.0 m/s. Reproduced from Gu, D., Rao, X., Dai, D., *et al.*, 2019. Laser additive manufacturing of carbon nanotubes (CNTs) reinforced aluminum matrix nanocomposites: Processing optimization, microstructure evolution and mechanical properties. *Addit. Manuf.* 29, 100801, Used with permission.

Graphene was added in three weight percentages of 0.5, 1 and 2.5 respectively. Formation of aluminum carbide (Al_4C_3) observed from XRD analysis, and the results showed an increase of 75.3% in hardness (Vickers) of the fabricated composites as compared to the pure aluminum fabricated through 3D printing (Hu *et al.*, 2018). Graphene platelets have also been reinforced to pure aluminum and the resulting characteristics was compared with other aluminum based composites. Bartolucci *et al.* developed such aluminum-graphene composite using hot isostatic pressing. The main objective of their study was to investigate mechanical properties and compare the same with the CNT reinforced aluminum based composites. The results showed decrease in mechanical properties, which was attributed to the increased formation of aluminum carbide resulting in decreased tensile strength and hardness (Bartolucci *et al.*, 2011). A novel method was used to develop graphene reinforced aluminum matrix (Al-4Cu) nanocomposite containing 0–1 wt% reduced graphene oxide (RGO) (Khoshghadam-Pireyousefan *et al.*, 2020). The fabrication method comprised of high energy ball milling and molecular level mixing. An increase in grain refinement was reported with the increase in the RGO reinforcement. RGO content with graphene has led to the enhancement in the mechanical behavior. Mechanical properties such as ultimate tensile strength, yield strength, and hardness (Vickers) of the developed material were observed to increase by 78%, 49% and 44%, respectively as compared to the base Al-4Cu alloy (Khoshghadam-Pireyousefan *et al.*, 2020).

Nanocomposites containing aluminum as base matrix with B_4C and h-BN as reinforcements were fabricated by stir and ultrasound-assisted casting method (Harichandran and Selvakumar, 2018). One set of samples was prepared with 4 wt% B_4C , and

the other set was prepared with 2 wt% and 4 wt% B_4C , and 2 wt% h-BN. All the developed composites were subjected to mechanical testing. Results showed an improvement by 67% in tensile strength was observed in hybrid nanocomposites as compared to the base matrix. Composites with 6 wt% of B_4C showed maximum hardness and tensile strength. Enhancement in elongation and impact strength was observed in composites with B_4C (2 wt% and 4 wt%) and h-BN (2 wt%) (Harichandran and Selvakumar, 2018). Nanocomposites with nanostructured Al5083 as the base matrix and SiC nanoparticles (SiCnp) as reinforcements in varying proportions were fabricated using mechanical milling route (Tazari and Siadati, 2017). A decrease in grain size was observed with the increase in reinforcement (SiC) content. Increasing the SiCnp content, considerably improved microhardness. An improvement of 95%, 83% and 166% in the compressive strength, shear strengths, and microhardness respectively for the nanocomposite containing 5 wt% SiC (Tazari and Siadati, 2017) was observed. Mousavian *et al.* (2020) reported that changes in the fabrication process lead to an improvement in the properties of nanocomposites. β -SiC nanoparticles were reinforced in aluminum alloy A356. Nickel (Ni) and titanium (Ti) were also used for modifying the surface properties of SiC. The process involved two-way stirring, one in semi solid-state and other in liquid state. Hot rolling process was used to develop the nanocomposites. It was observed that while both Ni and Ti modifiers influenced the mechanical behavior of the developed composites, Ni resulted in maximum enhancement in the properties. An increase by 77%, 85%, and 70% in ultimate tensile strength, yield strength, and strain % was reported in Ni modified composites as compared to the base alloy (Mousavian *et al.*, 2020). A356 was also reinforced with ZrO_2 nanoparticles in 2.5 and 5 wt% using stir casting process (Harsha *et al.*, 2020). Developed composites were investigated for their mechanical properties and the properties were observed to increase with the increase in ZrO_2 weight percentage. An increase by 22.5%, 40%, 39.83%, and 23% were reported in hardness, yield strength, ultimate tensile, and ultimate compressive strength, respectively. However, decrease in elongation was observed, and this was due to the hard and brittle phases of ceramic particles present in the composite (Harsha *et al.*, 2020).

Several authors have reported damage caused to carbon nano-materials while being processed. This had resulted in mechanical energy consumption and unfavorable chemical reactions between matrices and nano-materials (Choi *et al.*, 2011). Due to this very reason, spherical structured fullerenes have also been attempted as reinforcement by researchers owing to their zero-dimensional characteristics. Kwangmin *et al.* (2014) reinforced aluminum with fullerene, in two steps. In the first step, fullerene was crushed into particles of small size and the small-sized fullerenes were mixed with aluminum powder using high energy ball milling. In the next step, composites in the form of sheets were fabricated using hot rolling process. The composites were evaluated for their mechanical behavior and the findings showed hardness of 222 Hv and yield strength of 740 MPa with only 2% volume fraction of fullerenes. Improvement in mechanical properties was attributed to grain refinement and dispersion hardening (Kwangmin *et al.*, 2014).

Aluminum Based Nanocomposites: Tribological Behavior

Tribological performance of aluminum composites is an important area of research. Use of solid lubricants as reinforcement is most suitable for tribological application. Solid lubricants used in aluminum composites include molybdenum di sulfide (MoS_2), tungsten di sulfide (WS_2), graphite, poly tetra fluoro ethylene (PTFE) and graphene.

Singh *et al.* (2018) made Al nanocomposites with WS_2 nanoparticles along with Al_2O_3 and SiC as reinforcements via powder metallurgy technique. They observed that 5 wt% of the nanoparticles resulted in minimum coefficient of friction and wear. Similar kind of investigation was conducted by Ahmadi and Siadati (2018), wherein TiO_2 and CuO nanoparticle additions to aluminum matrix resulted in improvement in mechanical properties. Yield strength increased from 87 MPa to 250 MPa and hardness on Vickers scale increased from 40 to 73 in comparison to the pure aluminum. The authors reported an improvement in anti-wear performance of aluminum with TiO_2 and CuO nanoparticles. Wear coefficient was found to be lower by half in comparison to that of the pure aluminum.

Tribological investigations have also been conducted using graphene nanoparticles in aluminum alloys. (Prashantha Kumar and Xavier, 2017) investigate the tribological performance of aluminum based nanocomposites using graphene as reinforcement. Graphene was added in 0.3, 0.6, 0.9 and 1.2 wt%. They observed substantial decrease in wear for the aluminum composites. Minimum wear was reported for composites containing 0.3 and 0.6 wt% of graphene (Fig. 7). Decrease in COF was reported with the addition of graphene. Minimum COF value observed for the composites for graphene based composites was 0.25 in comparison to the COF of 0.32 for aluminum. Thus, it is inferred that graphene improves tribological characteristics of aluminum. In another study (Prashantha Kumar *et al.*, 2019), the authors used graphene, SWCNT and MWCNT as reinforcements in AA 6061 alloy. They observed that graphene reinforcement resulted in maximum improvement in hardness and fracture toughness due to uniform dispersion and more grain refinement in comparison to the other two reinforcements. Further, due to its protective nature, graphene reinforcement also resulted in minimum wear in comparison to the other two reinforcements. In another study, (Tabandeh-Khorshid *et al.*, 2016) carried out an investigation using graphene in aluminum matrix with 0.1 and 1 wt% of graphene. It was observed that 1 wt% concentration of graphene resulted in minimum coefficient of friction and wear rate (Fig. 8). Results were attributed to the self-lubricating nature of graphene nano particles. From the above discussed literature, it is clear that the use of graphene nanoparticles owing to its intrinsic characterizes leads to the protective film formation between the sliding surfaces. Thus, the use of graphene shall further widen its scope in the field of metal matrix composites.

Applications and Challenges

There is increased interest in industries towards the requirement of lightweight materials particularly in automotive and aerospace industries and the dynamic loading environments prevalent in these applications, and in this regard aluminum nanocomposites are promising materials mainly due to their intrinsic properties such as increased strength, high temperature creep resistance (Moghadam *et al.*, 2014). Taking into account the market scenario and the global trends, aluminum nanocomposites could find potential applications in areas such as defense, electrical components, construction, biomedical, sports and recreation industry, nuclear industry, robotic parts, drones, etc. Fig. 9 presents a summary of the potential applications of aluminum nanocomposites. Recent advancements in the development of aluminum nanocomposites by additive manufacturing can further widen the scope of these nanocomposites. Higher thermal conductivity and enhanced strength also makes these nanocomposites suitable for braking applications particularly in aircrafts (Moghadam *et al.*, 2014). Thermal conductivity of these nanocomposites can be varied to suit computer thermal management applications.

Some challenges regarding the development of aluminum nanocomposites that need to be addressed include reinforcement agglomeration, inter-particle interactions and interfacial debonding (Borgonovo and Apelian, 2011). With proper choice of reinforcement content, appropriate synthesis route and optimal process parameters, the aforementioned aspects could be improved, which will further widen the application aluminum nanocomposites.

Conclusions and Future Scope

A summary of the processing routes, mechanical and tribological behavior of aluminum composites has been presented. It has come to the fore that additive manufacturing (AM) has evolved as an alternative and efficient processing route for development of aluminum nanocomposites. Drawbacks associated with aluminum micron-sized reinforced composites can be overcome by using nano-sized reinforcements. Addition of nano-sized reinforcements in aluminum results in improved mechanical and tribological properties even with their addition in small content. Carbon-based nanomaterials such as graphene and CNTs are promising reinforcements for aluminum. The load bearing capacity of the hard nanoparticles and the shearing capability of some of the reinforcements such as graphene, positively influences the mechanical and tribological behavior of these nanocomposites.

Future studies to be undertaken are towards development of cost effective nanocomposites by focussing on developing low cost and efficient synthesis methodologies. A concerted research effort is required towards optimizing the process parameters, augmenting AM with Al nanocomposites, understanding the synergetic behavior of hybrid nano-reinforcements and investigating the properties of these nanocomposites in extreme operating/working environments. Application-oriented research is of prime interest so as to design materials for specific industrial applications particularly for aerospace, automotive, electronics and sports applications.

Damping Characteristics of Metal Matrix Composites

Penchal Reddy Matli and Manoj Gupta, National University of Singapore, Singapore

© 2021 Elsevier Inc. All rights reserved.

Introduction

The mechanical, thermal, and tribological properties have emerged the metal matrix composites (MMCs) as a prominent structural material (Davis and Artz, 1995; Ibrahim *et al.*, 1991; Miracle, 2005). They also have an impact in automotive, submersible vehicles, and aerospace structure applications (Gupta *et al.*, 2012; Rawal, 2001; Zweben, 1992) that undergo dynamic loading conditions and temperature variations throughout their service life. There is a huge advantage in the pre-existed applications mainly in automotive, aerospace structures, and heavy machineries with high mechanical vibration and damping capability of material (Sastry *et al.*, 2001; Zhang *et al.*, 1993) which is a positive motive towards the tailored MMCs. The combined characteristics such as mechanical vibrations and damping properties will help in opting the material and attains a huge performance.

Lightweight composite materials remain higher damping capabilities (Shunmugasamy *et al.*, 2016) are of great interests to material designers satisfying ever changing demands in automotive, aerospace and marine sectors. The ability of a material to absorb and disappear the mechanical vibrations at the period of cyclic loading is called its damping capacity (Kumar *et al.*, 2017), which were not required to engineering applications as they affect structural stability and then material's efficiency. In general, many of the metals and alloys possess lower damping capacity (Li *et al.*, 2000) so they were limited in their applications and as well as the performance in dynamic structures. All the above observations conclude that there is huge demand for the materials with high damping capacity as they were capable of eliminating unwanted noise and vibration, enhancing vehicle and instrument stability.

In the context of highly advanced technology and modernization, the noise and vibration have become a notable prominent and hazardous impact mainly in the complex mechanical engineering systems. (Yang *et al.*, 2017). Additionally, the vibrations and the sound were efficiently eliminated by the application of Mg or Al based composites as a damping material. In spite of inconsistency, when compared to viscoelastic polymers the damping characteristics of Mg or Al based composites were much dominant than the dense materials (Gupta and Wong, 2015; Wu *et al.*, 2006). The conventional particles reinforced metal matrix composites (MMCs) with high strength and stiffness were refined with enhanced damping properties in the recognized line. While considering the advanced systems in mechanical engineering, the vibrations and sound have been not favorable and became one of the prominent ranges of threat with the vast evolution in the science and technology. This grabbed the damping materials a huge attention. The high specific stiffness, excellent energy/sound absorption properties, low density have marked light weight Mg, Al and their respective alloys as an assured engineering materials.

Metal matrix composites are the potential materials systems designed by the addition of BN, SiC, CeO₂, Sm₂O₃, B₄C, SiO₂, NiTi and metastable reinforcements into Mg or Al matrix to discriminate improvements in both, strength and damping capabilities (Kujur *et al.*, 2017, 2018; Matli *et al.*, 2020; Narasimalu and Gupta, 2006; Nguyen *et al.*, 2015; Parande *et al.*, 2016; Penchal Reddy *et al.*, 2018; Tekumalla *et al.*, 2019). Moreover, addition of such hard, high damping reinforcements in the matrix can modify the microstructure of metals and alloys altering energy dissipation sources. The varying volume fractions, size of the reinforcement and selecting high damping reinforcing materials will influence the damping capacity of the obtained MMC (Siva *et al.*, 2015). The potential of the MMCs have been an efficient class of modern engineering materials, which have been concluded from different structural applications.

The enhancement in the mutual relations in between density and MMCs damping properties will provide a way for evolution of improved materials and which helps in reducing weights in considerable range. Lesser damping capacity was exhibited by traditional structural materials such as steel and titanium (Lu *et al.*, 2009; Prasad *et al.*, 2015). So, the demand for materials with low density and high damping capacity have been raised gradually that can fulfill the above-mentioned applications. Efforts are being pursued thoroughly in developing lightweight high performance composite materials that are tailored to exhibit good mechanical properties and high damping properties (Rahiman and Smart, 2019; Shunmugasamy *et al.*, 2016). Owing to their lower densities, low cost, processing flexibility, heat treat treatment capability, reasonably high thermal conductivity, and low melting point aluminum ($\rho = 2.7$ g/cc) and magnesium ($\rho = 1.74$ g/cc) are most sought-after materials in design of several dynamic structures in semiconductor equipment, aerospace and defense sectors (Gupta and Wong, 2015).

Material selection in dynamic loadings is primarily based on specific stiffness (E/ρ), replacing magnesium with aluminum results in lower values of mass and inertia as both metals have similar specific stiffness. Further, the damping capacity of pure magnesium was found to be 10 and 100 times higher than the pure Al (Schaller, 2003) and 316 stainless steel (Nguyen *et al.*, 2015), respectively. These exceptionally higher damping values of light metals helps in dissipating energy effectively in automotive and electronic components, minimizing fretting damages (Anilchandra and Surappa, 2012). In spite of its high damping capacity magnesium has a dominant priority among all other lightweight materials. With the addition of hard reinforcing particles to the ductile metallic matrix i.e., Mg or Al assists to enhance stiffness and overall damping capacity. This helps in reducing the vibrational amplitude of the mechanical system effectively (Srikanth *et al.*, 2003; Srikanth and Gupta, 2001).

The overall damping enhancement of magnesium or aluminum alloys and its composites can be attributed to several mechanisms like microstructural defects, grain boundary damping, porosity, intrinsic damping capability of the particles, interface damping, thermoelastic damping, thermal mismatch between the particulate and the matrix (Lu *et al.*, 2009; Surappa, 2003).

Fig. 1 Various categories of processing of metal matrix composites.

The main aim of the present study is to concentrate on lightweight structural metals such as Al and Mg. This can conclude that the composites with high damping parameters were about to be established and the scope for future research have been determined.

Processing Routes for Metal Matrix Composites

Metal matrix composites (MMCs) have many advantages as compared to monolithic metals as discussed above so their applications are increasing day by day in various fields.

In order to optimize the microstructure and damping properties of metal matrix composites, a variety of processing methods have been developed by industry and researchers over the last two decades. Generally, MMC fabrication can be classified into three categories: (1) Liquid-State processing, (2) Solid-State processing, and (3) In-Situ processing. [Fig. 1](#) shows the various categories of processing of metal matrix composites.

Liquid State Processing

Squeeze casting

Molten metal is introduced into an open die. The dies are then closed so that the molten metal solidifies under pressure within the dies. The heat is rapidly transferred from the molten metal to the dies under high pressure and through the contact between the metal and the die surface. As a result, a fine-grain casting with little to no pore is produced using this method ([Surappa, 2003](#)).

Infiltration process

Liquid metal alloy is infiltrated into the porous forms of fibers/whiskers reinforcements. The volume fraction of the reinforcements usually ranges from 10% to 70%, depending on the level of porosity. Silica and metal-based mixtures are often employed as binder to retain the integrity and shape of the porous forms ([S-de-la-Muela et al., 2020](#)). The phenomenon of transferring of molten metal into a preform is defined as infiltration. In pressure infiltration or melt infiltration, the reinforcements are kept in the die primarily and then the molten alloy is drilled upon the reinforcements and allowed to solidify in the absence of external pressure.

Stir casting

Particulate reinforcements are mixed with liquid metal melt and the mixture then solidifies. Specifically, the pre-treated particles are inserted into the vortex of molten alloy, which is created by a rotating impeller. A problem arises during the stir casting process as the reinforcements are not uniformly distributed and form sediments in the molten alloy. Generally, up to 30% particles in the size of 5–100 μm can be incorporated into the metal alloy ([Ramanathan et al., 2019](#)). [Zhang et al. \(2006\)](#) developed magnesium composites via stir casting method. They have concluded that the damping capacity of 8 wt%TiC/AZ91 was higher than that of AZ91 alloy due to the addition of TiC particulates.

Spray deposition

Spray decomposition can be defined as the phenomenon of atomizing matrix material by which fine diffusion of droplets through the pressure controlled inert gas jets which were filled with heated reinforcement particles. They reported that the deposition of reinforcing elements to the matrix have modified the technique. The minimum reaction of reinforcement with matrix can be attained by higher production rate and solidification time ([Ramanathan et al., 2019](#)). The size and percentage of reinforcement determines the particles the particles distribution in the composite. [Zhang et al. \(1994\)](#) studied the effect of SiC and graphite particulates on the damping behavior of metal matrix composites by spray atomization and deposition technique. They have reported that the damping mechanism related to Al/SiC composites have assigned to dislocation damping, interface damping at low testing temperatures and grain boundary damping, interface damping at high testing temperatures. When compared to Al/SiC, the Al/Gr composites possessed low elastic modulus.

Fig. 2 Schematic diagram for DMD method.

Disintegrated melt deposition (DMD)

Gupta and Wong (2015) examined the novel “Disintegrated Melt Deposition (DMD)” that addresses the consequences that occurs with conventional casting.

The DMD technique helps in uniform distribution of reinforcement, the interfacial integrity among the reinforcement and the matrix which has strong influence on the mechanical properties. This DMD evolved from the spray atomization and deposition technique which developed earlier. This process was shown in Fig. 2.

In this process, through the central drilled hole in the graphite crucible, the composite melt was poured which was fabricated by mechanical stir casting. At a perpendicular to melt stream two linear argon gas jets disintegrates the stream of the melt. On the metallic substrate placed at a certain distance from the gas integration, the composite melt slurry was deposited subsequently. Nguyen *et al.* (2015) investigated the effect of adding metastable particles on the mechanical damping behavior of extruded Mg-Al₈₅Ti₁₅ composites using DMD. The addition of Al₈₅Ti₁₅ powder significantly enhanced the damping properties of magnesium.

Solid State Processing

Through solid state processing metal matrix composites can be developed with the bond between metal matrix and dispersed phase because of the mutual diffusion among them in the solid state with the elevated temperature and pressure. The main fabrication methods for solid state processing of metal matrix composites are powder blending and consolidation, and physical vapor deposition.

Vacuum/gas sintering

The good controllability and broad list of properties have made vacuum and gas pressure sintering, which is the most preferred sintering technique (Xiong *et al.*, 2018). This technique is very similar to high-energy ball milling and sintering, the contrast exists only next to compacting. Gao *et al.* observed that the alloys possess the minimum porosity, uniform microstructure, excellent mechanical and damping properties (Gao *et al.*, 2017) when the sintering temperature is raised to a particular temperature.

Powder blending and consolidation

Metal alloy powder is blended with ceramic whisker/short fiber/particles in dry condition. After blending, the mixture is further processed by cold compaction. These blended powders were uniaxially compacted to obtain billets of 36 mm in diameter and 40 mm in height at a pressure of ~100 bar. The green compacted billets were then subjected to sintering. Prior to hot extrusion, the compacted billets were homogenized at 400°C for 1 h and subsequently extruded at 350°C using a 150-ton hydraulic press to obtain cylindrical rods of ~7–10 mm in diameter. The extruded rods were used for characterization and testing. This method is usually used for the processing of aluminum and magnesium metal matrix composites. The schematic of the preparation process was pictured in Fig. 3.

Fig. 3 Schematic illustration of the preparation of composites using powder blending and consolidation. Reproduced from Zeng, X., Liu, W., Xu, B., Shu, G., Li, Q., 2018. Microstructure and mechanical properties of Al–SiC nanocomposites synthesized by surface-modified aluminium powder. *Metals* 8 (4). Available at: <https://doi.org/10.3390/met8040253>.

Diffusion bonding

This is a well-known solid-state processing technique which combines same or varied metals. The bond is formed by inter diffusion of atoms in clean metallic surfaces, with elevated temperature. The inter diffusion atoms at the metallic surfaces under pressure creates bonding between the metal matrix and reinforcements (Kandpal *et al.*, 2014). This fabrication method is widely used for aluminum or magnesium MMCs reinforced with continuous/discontinuous fibers.

In-Situ Processing

In-situ processing involves chemical reactions which result in the creation of reinforcing phase within a metal matrix (Sastry *et al.*, 2001; Shunmugasamy *et al.*, 2016; Zhang *et al.*, 1993). The reinforcements can be formed from the precipitation in liquid or solid. A fine and well distributed reinforcement have been developed by this process. In between the matrix and the reinforcing phase, a fine bonding was evolved. They have grabbed much attention by its significantly low fabrication cost and output is huge (Nukami and Flemings, 1995; Premkumar and Chu, 1995). Fig. 4 displays the fabrication of as-cast TiB₂/AZ91 composite by stir casting method. Cao *et al.* (Xiao *et al.*, 2020) studied the damping characteristics of TiC reinforced to Mg metal matrix composites. With the increase of volume percentage of TiC particles, the damping capabilities of TiC/AZ91D composite have also been enhanced.

Damping Characteristics of Mg and Al-Based MMCs

In the field of semiconductor accessories, defense and aerospace, the priority of the light weight metallic materials i.e., Al and Mg have been rapidly raised in making the mechanical systems. The lower density of Mg (1.74 g/cc) than Al (2.7 g/cc) and the static stiffness of Mg (40 GPa) less than that of Al (70 GPa) have emerged Magnesium (Mg) as a most preferred light weight metallic materials (Gupta and Sharon, 2010; Matli *et al.*, 2020). Besides, the ability of exhibiting good damping characteristics than all other light weight metallic materials of Mg has helped dissipating the stored strain energy in the equipment's (Anilchandra and Surappa, 2012). Here, the improved inherent stiffness and damping capacities that enhanced the applications of Mg and Al matrix composites in the different engineering fields.

Fig. 4 Schematic of fabricating the In-situ Al-TiB₂ nanocomposite.

The anti-vibration capability of a material can be demonstrated with the damping capacity. The stability of the instrument and improvement of vehicle can be attained by the unwanted mechanical vibration and noise in the high damping materials. Pure Mg exhibit remarkably high damping capacity, whereas the vast applications of the pure Mg have been prevented by its low-tensile strength and elastic modulus. So, the Mg-MMC possessing better mechanical performance and high damping capacity parallel was the main motto of this extensive research. The high damping capacity can be attained by Magnesium matrix and the high mechanical strength can be obtained by the reinforcements (Xiuqing *et al.*, 2007).

The capability of a material to suppress or prevent the vibrations is called as its vibration damping. This vibration energy was observed by the material and gets utilized in various other forms of energy such as heat energy etc. The resonating frequencies that were the functions of the material properties such as elasticity, density and its microstructure have a frequency spectrum to these vibrations. The general representation of a sinusoidal damped vibration equation (Manakari *et al.*, 2017) is as follows Eq.

$$y(t) = Ae^{-kt} \sin(\omega t + \Phi)$$

where t is the time; A is the initial amplitude; k represents the decay constant which is material dependent property; ω is the angular frequency; Φ is the phase angle; and frequency; f is the number of cycle per time unit equals $\omega/2\pi$. Damping factor is estimated as,

$$Q^{-1} = k/\pi f$$

Damping loss rate is a function of sample weight (m) and the average ratio of two adjacent peaks from amplitude-time plot. The below equation represents the damping loss rate:

$$\partial = \frac{1}{m} \ln \left(\frac{y_1}{y_2} \right)$$

The damping tests have been carried out on Mg or Al-based metal matrix composites using the resonant frequency and damping analyzer (ICME, Belgium). The results were presented and discussed in this article.

Damping Characteristics of Mg-Based MMCs

Kumar *et al.* (2017) studied the role of La on the microstructural and damping properties of Mg-3Al alloy composites prepared by disintegrated metal deposition (DMD) technique followed by hot extrusion. Fig. 5 shows the damping characteristics of extruded pure Mg and Mg-3Al-xLa ($x \sim 1, 2.5, 4$) alloys.

They concluded that the increase in the amount of Al, the damping properties of pure Mg have declined. Whereas with the addition of (1, 2.5, 4) La, the damping capacity of Mg-3Al alloys was increased. The presence of La (2.5%) exposed there is an enhancement in the damping of Mg-3Al alloy by the damping measurement. The addition of 3Al, 3Al-1La, and 3Al-4 La has decreased the damping loss rate. When compared to pure Mg, a little enhancement in the damping loss rate was in the 3Al-2.5La. A minimum time is taken for suppressing the vibrations by Mg-3Al-2.5La is concluded from the damping results. The addition of La has played a key role in enhancing the damping performance of Mg-3Al alloy.

Nguyen *et al.* (2015) developed Mg- Al₈₅Ti₁₅ composites using rapid microwave sintering assisted powder metallurgy technique. The damping properties of the Mg- Al₈₅Ti₁₅ have been examined for the first by them and the data tabulated in Table 1. Fig. 6 shows the damping characteristics of pure Mg and it's composites. The significant enhancement in the damping properties of Mg by the adding of Al₈₅Ti₁₅ metastable powder particles can be concluded from the obtained results. With the increased amount of particles there was a slight reduction in the resonant frequency but the resonant frequency for the pure Al is observed to be 4620 Hz. The Mg-9Al₈₅Ti₁₅ composites exhibit a damping loss rate of 30 which is 3.75 times of pure Mg that is 8. A collaborative role has been played by the various damping mechanism such as twinning, microstructural defects and thermal mismatch.

Fig. 5 Damping properties of Mg-3Al and Mg-3Al-xLa ($x = 1, 2.5, 4$) alloys.

Wakeel *et al.* (2018) fabricated Mg-NiTi nanocomposite using the microwave sintering assisted powder metallurgy technique. The final values of damping and elastic modulus of the fabricated materials were represented in the Table 1. The addition of NiTi particles has enhanced its damping loss rate. Whereas the damping capacity of the Mg-2NiTi nanocomposite have obtained a value near to 21 that was 2.6 times higher when compared with the pure Mg. The damping capacity of the Mg-2NiTi nanocomposite attained significant improvement (with a value of 0.0008) that was 119% higher than the pure Mg. By introducing the NiTi SMA nanoparticles have attained a considerable enhancement in the damping characteristics of the pure Mg.

Gururaj *et al.* (Parande *et al.*, 2016) examined the damping characteristics and microstructure of Mg-SiO₂ nanocomposites using the assistance of hybrid powder metallurgy technique. Table 1 listed the damping characteristics of pure Mg and Mg-SiO₂ nanocomposites. The damping properties of the pure Mg have been enhanced significantly with the addition of SiO₂ nanoparticles. There is an enhancement in the damping loss rate by the addition of SiO₂ NPs. The maximum value of damping loss rate of *64 (*7 times of the pure Mg) has been possessed by the Mg-2 vol% SiO₂ nanocomposites.

Gururaj *et al.* (Parande *et al.*, 2018) developed Mg- β -tricalcium phosphate composites via hybrid powder metallurgy method. The damping characteristic of pure Mg and Mg vol%-TCP composites was represented in Fig. 7.

The elastic modulus, damping capacities and damping loss rate of the composite samples can be known from Table 1. As the amount of β -TCP increased the damping loss rate (L) and the damping capacity (Q^{-1}) enhanced. The best values for damping loss rate (L) and the damping capacity (Q^{-1}) is attained with Mg-1.5 TCP are ~ 17.7 and $\sim 7.59 \times 10^{-4}$, respectively, which was $\sim 109\%$ and $\sim 15.7\%$ to that of pure Mg.

Sravya *et al.* (Tekumalla *et al.*, 2019) fabricated E21-B4C composite by disintegrated melt deposition phenomenon and hot extrusion. They reported that there was no significant variation in the damping capacity and Young's modulus with respect to E21-1.5B4C Mg alloy whereas in the context of E21-2.5B4C Mg alloys a marginal increase was observed in the damping capacity and Young's modulus. From the above, we can conclude that the E21-2.5B4C nanocomposites possess the highest Young's modulus and best damping capacity. This attains lots of applications to thus nanocomposites in the suitable aircraft applications in addition to the present seat frames.

The effects of presence of SiC particulate reinforcement in Mg matrix have been examined by Srikanth *et al.* (Narasimalu and Gupta, 2006). The overall damping capacity of the ductile metallic matrix have enhanced with the inclusion of hard reinforcing particulates that can be concluded from the studies.

Table 1 Damping characteristics of Mg based composites

Composition	Processing method	Damping capacity ($\times 10^{-4}$)	Damping loss rate	Elastic modulus (GPa)
Pure Mg	DMD + HE (Kumar <i>et al.</i> , 2017)	8.00 ± 1.000	0.000456	–

Mili *et al.* (Kujur *et al.*, 2017) developed Sm₂O₃ nanoparticles reinforced Mg composites using hybrid microwave sintering and hot extrusion. The amplitude-time plots of respective samples have been represented in Fig. 8. The characteristics of the pure Mg and its composites such as damping capacity, damping loss rate and elastic module were listed in the Table 1.

With the increase in the amount of Sm₂O₃ NPs, the damping capacities and the damping loss rate of pure Mg have been enhanced. A significant increase in the damping capacity was achieved with the inclusion of Mg-1.5 vol% Sm₂O₃ (which is ~4.5 times that of a pure Mg). The Mg-Sm₂O₃ composites exhibiting damping properties with nearly same elastic modulus of the human bone made it as an efficient for implant material.

Vyasraj *et al.* (Manakari *et al.*, 2017) synthesized hollow glass microspheres (5, 15 and 25 wt%) reinforced magnesium composites using the disintegrated melt deposition (DMD) method and studied its damping properties. The ability of a material to absorb vibration can be known as damping loss rate (L), which is showed an increase with the addition of glass microspheres (Fig. 9a). Damping loss rate of Mg-25 composite increased by 12.5 times when compared to pure Mg and exhibited a linear relationship with increasing amount of reinforcement.

Damping capacity of Mg-25 composite increased by 370% when compared to pure Mg and exhibited a linear relationship with increasing amount of reinforcement. Damping capacity (Q^{-1}) of Mg also seen to be increasing with the increasing filler loadings (Fig. 9b).

Damping Characteristics of Al-Based MMCs

In general, the damping capacity possessed by Al was comparatively low. Through the thermal mismatch strain induction, the matrix microstructure including reinforcement and dislocation in the matrix were attained by MMC fabrication techniques.

The microstructural and damping response of Al-NiTi nanocomposites have been investigated by Penchal *et al.* (Matli *et al.*, 2020) using microwave with the assistance of two-directional rapid sintering and hot extrusion successively. The amorphous Ni₅₀Ti₅₀ reinforcement (0.5%, 1% and 1.5 Vp.%) materials and the Al matrix are the requirements for this process. A composite

Fig. 9 Linear fitted curves for: (a) Damping loss rate, and (b) Damping capacity as a function of GMB content.

powder was fabricated by ball milling the prepared powders for 120 min at a speed of 200 rpm. At a compaction pressure of 97 bar (50 tons), blended powders were compressed. A cylindrical billet of 40 mm and 35 mm diameter is acquired. At a temperature of 550°C, through hybrid microwave set-up the compacted billets were sintered. To produce an extruded rod of 8 mm diameter, the sintered billet was hot extruded at 350°C at an extrusion ratio of 20.25:1.

Through the resonance frequency damping analyzer (RFDA) the damping property measurements was conducted. Fig. 10 and Table 2 represents the Vibration damping capabilities of pure Al and Al-NiTi nanocomposites. With the incorporation of NiTi nanoparticles greater/equal to one volume percent, the damping capacity (Q^{-1}) and the damping loss rate (L) of the pure Al were found be enhanced significantly. The optimum values of damping capacity and damping loss rate at ~ 6.15 and $\sim 17.15 \times 10^{-4}$, were acquired for Al-1.5 NiTi nanocomposite were obtained respectively in this investigation. When compared to pure Al, the damping capacity and damping loss rate for the nanocomposite sample was enhanced by $\sim 15.4\%$ and $\sim 16.2\%$.

Fig. 10 Damping characteristics of Al- $\text{Ni}_{50}\text{Ti}_{50}$ nanocomposites.

Penchal Reddy *et al.* (2018) studied the Al/BN nanocomposites can be developed by two-directional microwave assisted rapid sintering. The processing details were similar to earlier studies in Penchal *et al.* (Matli *et al.*, 2020). The amplitude-time plot of pure Al and Al-BN nanocomposite specimens was represented in Fig. 11.

The damping properties of pure Al and its Al-BN (0.5, 1 and 1.5 vol%) nanocomposites were tabulated in Table 2. In the free vibration mode, every specimen's vibration response obtained is factor of time and amplitude. The results conclude that for every material, there is a varied amplitude and different time taken by vibration to prevent the amplitude. The damping characteristics of the pure Al have been increased by the inclusion of nano-BN particulates as reinforcement. Fig. 11 concludes that there is a sudden decline in the amplitude of Al-BN nanocomposites whereas pure Al has a periodic fall in the amplitude. Vibrations are damped in less than ~ 0.27 s for Al-1.5 vol% BN nanocomposite. The gradually addition of nano-BN particulates have resulted with a dominant improvement in the damping capacity (Q^{-1}). The Al-1.5 vol% BN nanocomposite gave a maximum damping capacity of 0.000676 (which is 26.8 times that of pure Al). Then, the resonant frequency for pure Al was found to be 8846 Hz whereas the addition of nano-BN particulates with varied vol% such as (0.5, 1.0 and 1.5) BN nanocomposite resulted in a slight decrease of the resonant frequency, the values were found to be 8573, 8528 and 8492 Hz, respectively. When compared to pure Al, the benefits such as reduced resonant frequency and vibration amplitude have led to overall damping capacity of the nanocomposites. Fig. 12.

Through Disintegrated deposition method (DMD) technique, Narasimalu *et al.* (Narasimalu and Gupta, 2006) investigated the damping behavior of Al (AA1050) alloy-SiC composites. The results concluded that there is an overall enhancement in the damping capacity of Al matrix with the addition of SiC ($\sim 25 \mu\text{m}$ size) to the matrix and presence of interconnected Fe wire. The presence of Al with 0.5 vol% of SiC and 2 vol% of interconnected Fe wire, jointly exhibits a damping capacity 25% higher than that of pure Al, whereas interconnected Fe wire lonely provides only 15% higher than that of pure Al and there was a 10% variation when compared with SiC particulates and Fe wire. So, the presence of both SiC particulates and Interconnected incorporates to attain the best damping capacity to the Al.

Madeira *et al.* (2016) studied Al composites reinforced with SiC particles. The result reports that the particle size and the frequency were directly proportional to the damping capacity whereas the particle size decreases the dynamic modulus. Zhang *et al.* (1994) studied 6061 Al/SiC and 6061 Al/Gr composites and compared with that of Al alloy. This study concluded that the damping capacity was enhanced with the reinforced composites unlike unreinforced alloys. The damping capacity of the graphite reinforcement is volume fraction dependent, whereas SiC is volume fraction independent.

Table 2 Damping characteristics of Al based composites

Composition	Processing method	Damping capacity ($\times 10^{-4}$)	Damping loss rate	Elastic modulus (GPa)
Pure Al	PM + MWS + HE (Matli <i>et al.</i> , 2020)	5.33 ± 0.056	14.76 ± 0.09	71.65 ± 0.02
Al-0.5 vol% NiTi		4.17 ± 0.031 ($\downarrow 21.7\%$)	11.65 ± 0.06 ($\downarrow 21\%$)	75.99 ± 0.02 ($\uparrow 6.05\%$)
Al-1.0 vol% NiTi		5.65 ± 0.029 ($\uparrow 6\%$)	15.2 ± 0.06 ($\uparrow 2.98\%$)	76.48 ± 0.01 ($\uparrow 6.74\%$)
Al-1.5 vol% NiTi		6.15 ± 0.029 ($\uparrow 15.4\%$)	17.15 ± 0.06 ($\uparrow 16.19\%$)	75.93 ± 0.08 ($\uparrow 5.97\%$)
Al-0.5 vol% BN	PM + MWS + HE (Penchal Reddy <i>et al.</i> , 2018)	5.88 ± 0.073 ($\uparrow 10.3\%$)	15.78 ± 0.11 ($\uparrow 6.91\%$)	71.88 ± 0 ($\uparrow 0.32\%$)
Al-1.0 vol% BN		6.18 ± 0.039 ($\uparrow 15.9\%$)	16.48 ± 0.09 ($\uparrow 11.65\%$)	72.2 ± 0.006 ($\uparrow 0.76\%$)
Al-1.5 vol% BN		6.76 ± 0.042 ($\uparrow 26.8\%$)	18.3 ± 0.07 ($\uparrow 24\%$)	73.08 ± 0.017 ($\uparrow 2\%$)

**Fig. 11** Damping characteristics of pure Al and Al-BN nanocomposites.

Summary and Conclusions

The main aim of the current article was to draw the attention among the damping characterization and the fabrication processes of the MMCs in addition to product application. The following are the respective conclusions from this article:

- (1) In this article, we have briefly gone through most commonly used fabricating techniques to manufacture MMCs, in which DMD and PM were mostly employed. In the enrichment of damping properties, Secondary fabrication process such as extrusion was employed successfully.
- (2) The types of matrix, reinforcements (individual, multiple, percentage, size, distribution in matrix), wettability and reaction during the fabrication process were the factors influencing the damping characteristics of the matrix.
- (3) During the past few decades, there were several studies was competed on Mg and Al MMCs to attain a conclusion and introducing them in the progressively developed industries. To acquire the complete knowledge on the collaboration of processing route, microstructure, and damping properties, a great research has been done.

Fig. 12 Fitted curves for: (a) Damping loss rate, and (b) Damping capacity as a function of amount of reinforcement (BN).

- (4) In the fields of space technology, aircraft industry, automobile component, electrical and electronic field, and other product applications, the demand for usage of MMCs have prominently enhanced. Besides, to examine the MMCs usage in the context of cost and good performance, they reported that an exclusive research is required.

Introduction

The advancement in the technology has changed our life, the manner in which we live, learn, communicate, travel and at the same time, simplified our life by saving time, improving communication, providing better health care services etc. Both our professional and personal life is extremely dependent on the advanced technology. The increasing use of communication technology and electrical/electronic devices has generated problems of electromagnetic radiation pollution (Yang *et al.*, 2018; Che *et al.*, 2004; Yang *et al.*, 2015; Song *et al.*, 2017). These undesired electromagnetic radiations not only affect the lifetime and performance of source electronic devices, but also interfere with the functioning of other nearby devices and create a problem of electromagnetic interference. Electromagnetic interference (EMI) is an undesired disturbance from the electromagnetic radiation that affects the normal functioning of the electrical circuits or devices. The sources of electromagnetic interference may be any natural or artificial objects that can generate radiated (electromagnetic waves) or conducted emission (noise). When a sensitive device comes in vicinity of the unwanted signal generated by certain other electrical or electronic circuit, disturbance in the form of EMI effect can be observed and these EMI disturbances may cause interruption, obstruction or complete degradation of the device performance (Zhang *et al.*, 2015b; Lee *et al.*, 2017b). Because of the reason of EMI, use of cell phone is limited inside an aeroplane or automated robotic operation theaters to avoid electronic failures. Moreover, the fast growth in scientific devices, military/aerospace instruments, industrial equipment, electronic and telecommunications system has developed a threat of EMI as the electromagnetic radiations are the leading cause of impairment in electronics, telecommunications, and aerospace components and devices. Therefore, need for a shielding mechanism arises to protect electronic devices from unwanted electromagnetic pollution and to make sure that device will work with other nearby electronic instruments without compromising the performance and disruption in device functioning.

This process of reducing the effect of electromagnetic radiation in a space with the help of some barrier or shield is called as EMI shielding. A significant reduction in electromagnetic fields, electrostatics fields and radio waves can be achieved with mechanism of shielding. Typically, shielding can be referred as an enclosure used to isolate the electronic device and its components from external radiations. Thus, shielding is the practice through which certain level of reduction in electromagnetic field can be achieved using specially designed shields. Materials used for shielding are called EMI shielding materials and the amount of reduction in electromagnetic fields largely depends on the properties of shielding materials used, the size and thickness of the shield and the interested frequency range etc (Thomassin *et al.*, 2007; Cho and Kim, 1999).

EMI Shielding Materials

The increased demand of advanced electronic devices and the serious threat from electromagnetic pollution has motivated the scientific community to develop EMI shielding materials that work in a broad electromagnetic frequency range. Current modern specialized gadgets operate in a wide frequency range having different EM bands. Each EM bands have characteristic applications. For example, wireless communications and earth orbit satellites work in L-band (1–2 GHz), for sound and sight applications such as TV, mobiles, cordless telephones etc, the S-band (2–4 GHz) is utilized, the C-band (4–8 GHz) is used in Wi-Fi devices and radio telecommunication, X-band (8–12 GHz) finds applications in civil, military and aerospace industries for defense tracking, weather monitoring, air traffic control and speed detection of vehicles and the Ku-band (12–18 GHz) band is employed as a part of very small aperture terminal systems (Kumar *et al.*, 2015; Belov *et al.*, 2012). Thus, depending upon the specific applications novel EMI shielding materials will be needed that provide protection against electromagnetic radiations of particular frequency range.

Mechanism of EMI Shielding

There is wide variety of EMI shielding materials used in present scenario but depending upon the mechanism of shielding, each material shows its optimum EMI shielding characteristics in certain frequency range and under certain control parameters. Generally, there are three basic mechanism of shielding reflection, absorption and multiple reflections. Reflection is a surface phenomenon and shielding through reflection mechanism required a conducting shield surface having plenty of mobile charge carriers (electrons or holes) which can interact with the electromagnetic field. Hence, electrically conducting materials are preferred although a high electrical conductivity is neither essential nor it is a scientific criterion for shielding. As metal have high electrical conductivity, they are most commonly used for EMI shielding applications where reflection of electromagnetic radiation through

Fig. 1 Schematic representation of mechanism of EMI shielding.

the shield surface is required. Some of the metals used for shielding are copper, zinc, nickel, silver, gold, boron, tungsten, titanium or their combination materials (Tong, 2016; Azim *et al.*, 2006). Though, metals have good EMI shielding properties they suffer from corrosion, easy oxidation, low chemical resistance and poor processing methods. Moreover, metals are bulky due to high density, so metal coating is used for shielding purpose which can be made by electroplating or vacuum deposition techniques. But again it is susceptible to poor wear or scratch resistance properties.

Another important mechanism of shielding is the absorption. There are two important factors on which absorption properties of the shielding materials depends. They are the dielectric losses defined by electric permeability or dielectric constant and the magnetic losses defined by magnetic permeability. The high value of dielectric constant in a material is accountable for the generation of electric dipoles while high value of magnetic permeability is responsible for magnetic dipoles. Both electric and magnetic dipoles can interact with the electromagnetic radiations to reduce its impact (Li *et al.*, 2011; Qin and Brosseau, 2012). Based on these concepts, it is suggested that absorption mechanism required either purely dielectric materials having magnetic permeability value unity i.e., $\mu = 1$ or dominate in materials which have magnetic permeability and electric permittivity value different to one. Besides reflection and absorption, shielding can be achieved through the mechanism of multiple reflections occurs at various surfaces/interfaces present in the shielding materials. High surface area or interfacial area is the prime requirement for this mechanism. For example, porous or foam material have high surface area while composite material containing filler is an example of large interfacial area. The effect of shielding due to multiple reflections can be ignored if the distance between the reflecting surfaces/interfaces is greater than the skin depth.

Commonly, at higher frequency the electromagnetic radiations penetrate the near surface region of an electrical conducting material and electromagnetic field drops exponentially with the depth of the conducting material. This condition is called as skin effect and the depth to which fields drops to $1/e$ of the incident value is called as skin depth (Gupta *et al.*, 2013b; Zhang *et al.*, 2011). $\delta = \frac{1}{\sqrt{\pi f \mu \sigma}}$, where, f is the frequency, μ is the magnetic permeability ($\mu_0 \mu_r$), μ_0 is permeability of free space $4\pi \times 10^{-7}$ H/m, μ_r is the relative magnetic permeability and σ is the electrical conductivity in $\Omega^{-1} \text{ m}^{-1}$.

Generally, the mechanism of EMI shielding through multiple-reflections is slightly complex shown in Fig. 1. The effect of multiple-reflection is usually irrelevant in case of a highly conducting EMI shielding materials because most part of the incident electromagnetic radiations are reflected back from the conductive shield surface and limited part of electromagnetic radiations can be penetrated through the shield surface to be remains available for multiple-reflections phenomenon. On the other hand, the contribution of multiple reflections became more important in case of materials with low conductivity and high permeability. Since, electromagnetic radiations can easily penetrate inside the shielding material and most part of it is reflected and absorbed inside the surface of the shield material. The effect is more significant in low frequency while at higher frequency it reduces as the ratio between thickness of the materials and skin depth (t/δ) become larger with the increase in frequency range.

Composite Materials for Shielding

Traditional metal-based EMI shielding materials are unsuitable for advanced EMI shielding application. They are bulky and mainly work through reflection of EM radiations and cannot be used in applications where lightweight shielding materials are required like in aerospace and space structures. Furthermore, they are undesirable for applications where absorption is prime requisite. To overcome these limitations, composite materials are explored as EMI shielding materials. A composite can be a blend of two or more materials with different chemical and physical characteristics which synergized effect of each other. Therefore, it is expected that the composite system can provide better properties (physical, structural or functional) as compared to the individual constituents (Anisha *et al.*, 2018; Dhakate *et al.*, 2016). Additionally, composite materials sometimes used to redesigned one characteristic of material to overcome another characteristic. In general, composite consist of two phases i.e., continuous phase or matrix and dispersed phase or reinforcement and for composite preparation, reinforcing particles are added to the base structure i.e., matrix of another material. Since, both matrix and reinforcement phases are available in large varieties, different type of composite materials are available for EMI shielding applications. Matrix can be made of metallic, inorganic, polymeric materials and reinforcing phase can be of fibers, particles, crystals etc.

Metal matrix composites

Despite of the heavy weight problem, metals are widely used as an EMI shielding materials due to inherent advantage of high electrical conductivity (perfect ground plane for on-board electronics), EMI shielding capabilities, static charge dissipation properties etc. Therefore, researchers are paying attention to develop metal matrix composites which possess superior combination of physical/mechanical properties. As the name suggests, metal matrix composite made of matrix of metal in which reinforcement fibers or particles are uniformly embedded. Sometimes metals are also used as reinforcement in polymeric or carbon-based matrices.

Metal plate shielding theory

The capabilities of EMI shielding materials are measured in terms of shielding effectiveness (SE) value. It is defined in terms of the logarithmic ratio of incoming power (P_i) to the outgoing power (P_o) of an electromagnetic radiation falling over the materials and is expressed in decibel (dB). The shielding effectiveness values are in negative terms as outgoing power is always less than incoming power. When an EMI shielding material comes in contact with electromagnetic radiation, phenomena such as reflection, absorption and multiple reflections can be observed. Therefore, the total EMI shielding effectiveness is the sum of shielding effectiveness due to reflection (SE_R), absorption (SE_A) and multiple reflections (SE_M) and can be written mathematically in the logarithmic scale as (Gupta *et al.*, 2013b; Zhang *et al.*, 2011; Singh *et al.*, 2011b)

$$SE_T(\text{dB}) = SE_R + SE_A + SE_M = -10 \log(P_o/P_i) = -10 \log(H_o/H_i) = -10 \log(E_o/E_i) \quad (1)$$

Where, P_i & P_o are incoming power and outgoing power, H_i & H_o are the incoming and outgoing magnetic field strength and E_i & E_o are the incoming and outgoing electric field strength of electromagnetic radiation, respectively.

If the EMI shielding materials have higher shield thickness than the skin depth, the contribution of shielding effectiveness value due to multiple reflections can be neglected. In such situation, reduction in electromagnetic radiations occurs either by reflection phenomenon or absorption phenomenon and the total EMI shielding effectiveness (SE_T) can be expressed as (Gupta *et al.*, 2013a; Singh *et al.*, 2013; Ohlan *et al.*, 2008).

$$SE_T(\text{dB}) = SE_R + SE_A \quad (2)$$

Furthermore, SE_R and SE_A can be measured in terms S-parameter S_{11} (S_{22}), S_{21} (S_{12}) corresponds to reflection and the transmission coefficients, respectively;

$$T = [E_T/E_i]^2 = [S_{21}]^2 = [S_{12}]^2 \quad (3)$$

$$R = [E_R/E_i]^2 = [S_{11}]^2 = [S_{22}]^2 \quad (4)$$

The effective absorbance, A_{eff} is expressed as:

$$A_{\text{eff}} = (1 - R - T)/(1 - R) \quad (5)$$

Consequently, regarding the incident power of electromagnetic radiation falling over a shielding material, having R as the reflectance, SE due to reflectance and absorbance can be given by the expression:

$$SE_R = -10 \log_{10}(1 - R) \quad (6)$$

$$SE_A = -10 \log_{10}(1 - A_{\text{eff}}) = -10 \log_{10} \left[\frac{T}{(1 - R)} \right] \quad (7)$$

Electromagnetic radiation comprises of two fundamental components, a magnetic field (H) and an electric field (E). Both the fields are perpendicular to each other and at right angles to the plane of electromagnetic radiations containing the two components. The waveforms and its source decide the relative magnitude and ratio of E to H is defined the wave impedance. Depending upon the distance between the electromagnetic source and the shield material, electromagnetic shielding divided into near field region or far field region relative to the wavelength (λ) of the electromagnetic wave. If the distance between the electromagnetic radiation source and the shield is greater than $\lambda/2\pi$ it is called as far field shielding region whereas if this distance is less than $\lambda/2\pi$, it is the near field shielding region.

In far field shielding region, the electromagnetic waves can be considered as plane waves and both electric field (E) and magnetic field (H) are responsible for the EMI effects and satisfy the condition

$$Z = [E]/[H] \quad (8)$$

Where, Z is the wave impedance or the intrinsic impedance $[E]$ and $[H]$ are the amplitude of electric and magnetic field, respectively. For free space impedance value is always equal to 377Ω .

In case of near field shielding region, wave front is not planer but it is curved and hence, it is not parallel to the shield surface. In such situation impedance $[E]$ and $[H]$ amplitudes are not constant and depends on the distance or on the dominant field for example in an electrical radiation source, electrical field dominates over magnetic field. The intrinsic impedance is greater than 377Ω which decreases as the distance increases.

Lightweight EMI Shielding Materials

High performances EMI shielding is needed for modern electronic devices but lightweight is one of the important technical prerequisites for various EMI shielding applications especially in automobiles and aerospace industry. In lightweight EMI shielding materials polymer-based composite, aerogels and foams are attracting materials.

Polymer-Based Composites

Polymer-matrix composites possessing conductive filler has been used for EMI shielding applications because of their film forming ability which reduces or eliminates seams in the shield housing. Basically, seams are encountered in metal housing where they have a tendency of radiation leakage and consequently a diminish shielding effectiveness observed in such shield. Besides this, polymer-based composites possess low density hence suitable for lightweight shielding applications (Nimanpure *et al.*, 2018a,b). Polymer matrix is generally non conducting hence some conducting filler materials are required to improve the conductivity of the polymer matrix. Polymer-conductive filler composites can be used as a promising material for advanced EMI shielding applications such as polymers containing metallic filler or carbon based electrically conductive filler. Metallic fillers in the form of fibers or nanoparticles are dispersed in the polymer matrix to enhances the electrical conductivity of the matrix and for better interaction with the electromagnetic radiations. Injection molding is the most commonly used method for dispersion of metallic fillers in the polymer matrix (Chen *et al.*, 2008; Shyr and Shie, 2012). Drawbacks of these type of polymer composites are that the weight of the composite increases in an attempt to achieve uniform dispersion of the metallic fillers in the polymer matrix. Recently, much work has been carried out on the conducting polymers-based composites. The conductive polymer composites are advantageous because of the lightweight, low cost, film forming ability of the polymer, design flexibility, ease of processing and more importantly, the incorporation of fillers in low amount keeps the polymer being transparent to the incoming electromagnetic radiations. Most commonly used conducting polymers are polyaniline (PANI), polyacetylene, and polypyrrole etc (Lakshmi *et al.*, 2009; Singh *et al.*, 2011a). These polymers are conjugated polymers and on doping show electrical conductivity. Contrast to metallic filler which impart conductivity to the polymer matrix, molecular structure imparts electrical conductivity in case of conducting polymers. Optimization of parameters such as molecular size, polymer loading, polymer type and the synthesis process can lead to enhanced EMI shielding properties of these composites. From commercial point of view, such polymer-polymer composite framework is advantageous because lightweight being achieved with no issue of substrate flexibility as compared to those arises in the metallic or carbon-based fillers. However, these composites have some disadvantages like poor mechanical properties hence a matrix material is always required to support the structure, poor processability problem and requirement of higher filler loading for exhibiting better EMI shielding properties.

Principle points of interest of such polymer-polymer system are that the lightweight being accomplished, with no issue of substrate adaptability as those emerges in the metallic or carbon-based fillers.

Carbon based filler are extensively used to develop polymer composite for EMI shielding applications. Like metallic fillers carbon-based filler are available in various forms and aspect ratio (length to width ratio) (Nazir *et al.*, 2018; Al-Saleh *et al.*, 2013; Kim *et al.*, 2014). In general, carbon materials with high aspect ratio impart better electrical conductivity to polymer matrix. Thus, materials with high aspect ratio shows high EMI shielding effectiveness values if the filler volume fraction remains same. Whereas carbon fillers with aspect ratio are Single walled carbon nanotubes > Multiwalled carbon nanotubes > carbon nanofibers > Carbon black. Besides these fillers, using a combination of two or more types of fillers provides an efficient method to overcome the shortcomings of a single filler composites. For example, incorporation of a magnetic filler will boost the EMI shielding capability of a carbon-based EMI shielding material.

Chizari *et al.* reported the highly conductive 3D printable inks fabricated from nanocomposites of carbon nanotubes/poly(lactic acid) (CNT/PLA) with outstanding electrical conductivity up to $\sim 5000 \text{ S m}^{-1}$ (Chizari *et al.*, 2017). They used solvent-cast 3D printing to produced conductive scaffold microstructures and studied the effect of several significant basic parameters like number of layers, IFC and printing patterns on the transparency and EMI shielding effectiveness. The outcomes revealed a substantial improvement in the specific EMI SE of CNT/PLA nanocomposites printed as 3D scaffolds in contrasted with CNT/PLA hot-pressed in solid forms (~ 70 versus $\sim 37 \text{ dB g}^{-1} \text{ cm}^3$). The transparency of the frameworks could vary from $\sim 0\%$ to $\sim 75\%$ by altering their printing designs and inter-filament spacing. The reported work is highly beneficial for the manufacture and auxiliary advancement of EMI shields where light as well as transparent structures are important, for example, in aviation structures, advanced lightweight electronic gadgets or smart fabrics.

Foams and Aerogels

The specific EMI shielding effectiveness (EMI SE) is defined as total EMI SE shielding effectiveness divided by the density of the material or both density and thickness of the material. Specific EMI SE is the standard method to compare the performance of the EMI shielding materials having different density or thickness values, especially in applications where lightweight is the prime requirement. Foam structure-based composites have recently gained attention as promising EMI shielding materials due to their low density and interconnected conductive structure. The interconnected porous structure improved the shielding effectiveness through scattering or multiple reflections inside the pore walls. For example, electrically conductive fillers materials such as

Table 1 Percentage of shielding efficiency with the shielding effectiveness value according to the Eq. (1)

SE (dB)	20	30	40	50	60
Shielding efficiency (%)	99	99.9	99.99	99.999	99.9999

graphene sheets, CNTs and CNFs are used to form a conductive network structure within an insulating polymer foam matrix. Some syntactic foam like structures having hollow spheres in a matrix are also developed as lightweight EMI shielding materials. Recently, carbon foams have explored extensively for lightweight EMI shielding applications due to their low density, high surface area, interconnected conductive network and good thermal stability (Kumar *et al.*, 2013b; Zhang *et al.*, 2016). Carbon foam is a sponge like three dimensional (3D) interconnected structure of porous carbon. Earlier, carbon foams were prepared by heat treatment of thermosetting plastics in controlled conditions, later on coal tar pitch or petroleum pitches were used to prepared carbon foams. For the advanced lightweight shielding materials requirement, one dimensional (1D) CNTs or two-dimensional (2D) graphene sheets are used as filler materials into three dimensional (3D) porous structures (e.g., sponges, foams and aerogels) for achieving high EMI shielding performance with low density (Lu *et al.*, 2018; Zhang *et al.*, 2017; Wu *et al.*, 2017).

Besides foam structure, aerogel-based materials are widely explored lightweight EMI shielding applications, Aerogels as the name suggest, is a gel like porous ultralight material, in which liquid components commonly present in gel is replaced by the air. Graphene aerogels are generally used as promising EMI shielding materials (Singh *et al.*, 2015; Song *et al.*, 2015a; Liu *et al.*, 2018). A comparison of electromagnetic interference shielding effectiveness of different polymer based composite materials reported in literature are shown in Table 1.

EMI Gaskets

EMI gaskets are mechanical seams or casing that help to protect electronics devices from electromagnetic interference. EMI gaskets work by setting up a conductive path along seams and different openings in an electronic enclosure. It blocks potential difference across the shield surface to builds up a smooth current stream. Generally, gaskets plug every one of the openings in a piece of device, so that EMI radiation does not interfere with the functioning of the device. Previously, these gadgets were essentially found in radio communication and military instruments, yet because of the fast increment in EMI radiation, gaskets are normally found in the various of electronic gadgets. Mostly, gaskets must be utilized when EMI surpasses 60 dB value. Gaskets expected for EMI shielding applications are indicated to be of a construction which not only offers electrical surface conductivity even under pressure, but which also has a versatility enabling the gaskets to fit in the size of the gap between EMI shielding required structures. Additionally, the gasket materials should be durable, lightweight, economical and flexible enough to withstand repetitive compression and relaxation processes.

EMI shielding gaskets generally built as a robust core which is filled, covered or coated with an electrically conductive material. The core element typically is made of an elastomeric thermoplastic material for examples polypropylene, polyethylene, polyvinyl chloride or a thermoplastic/thermosetting rubbers such as a nitrile, chlorosulfonate, butadiene, styrene-butadiene, urethane, or silicone rubber etc., (Mottahed and Manoochehri, 1997; Shui and Chung, 1997; Zhu *et al.*, 1998; Lee, 1995). Depending upon the type of shielding required various types of gasket materials are available. Silver- or nickel-plated filler based conductive elastomers are more suited where small, precise cross sections are desired. Conductive elastomers in automated form-in-place EMI gasketing systems are also employed for enclosure parts, like wireless handset. The automated robotic system uniformly spread conductive elastomer onto metal surface or metal coated plastic housings with precise accuracy. Foam-based gaskets are used for providing shielding under low closure forces such as conductive fabric, wire mesh or metal foil over soft foam. Conductive elastomers (hollow or solid extruded) are typically used for wireless enclosure doors, panels and covers. These gaskets are more appropriate for outdoor applications as they can provide protection from both EMI and environmental risks such as moisture, corrosion etc. Knitted wire mesh type EMI gaskets, extensively used for shielding applications from so many years and now adjusted accordingly for wireless shielding design requirements. Tin-plated steel wire knitted gaskets gives a spring-like versatility when groove mounted in cast metal enclosures. The present wire mesh gaskets can divert 80% of radiations under low closure forces, permitting the utilization of more affordable enclosures area. Metal finger stock gaskets used high level of EMI shielding abilities with spring-finger wiping activity and low closure characteristics. Commonly beryllium copper (BeCu) is used for these types of gaskets. Finger stock gaskets are very flexible and impervious to pressure set. They are generally used on base station entryways where shear forces are experienced. In multiple board phones, a typical protecting approach utilizes spacer-type EMI gaskets made up of plastic and conductive elastomer. Spacer gaskets offer an EMI barrier between segments to secure against cross talk.

Different Types of Nanocomposites for EMI Shielding

Compared to conventional composites, nanocomposites are different because they contain at least one component having dimension in nanometer range (less than 100 nm) and good electrical, optical, thermal and mechanical properties. Most commonly used nanomaterials are metallic, ceramic or polymers (polyurethane, epoxy, nylon, polyepoxide, polyetherimide), ceramics

(alumina, glass, porcelain) while metals (iron, nickel, titanium) are generally used as a matrix material. As already discussed, composites contain two phases i.e., one is matrix and second is reinforcement or filler. But there is one other phase between the matrix and the filler called as interfacial phase or region which is accountable for the macroscopic properties of the nanocomposites which differ from the bulk composites. There are many challenges in the way to full exploitation of the nanocomposites such as uniform dispersion of the nanomaterials, understanding role of interfaces on bulk properties present between the different constituents, compatibility between the multiple nanomaterials. Due to their unique properties, nanocomposites are extensively investigated as potential EMI shielding materials for lightweight advanced technology.

Carbon-Based Composites and Their EMI Shielding Properties

The discoveries and research of new allotropic modifications of carbon materials have sparked considerable research interest for electromagnetic interference (EMI) shielding to address the problems of EMI pollution. As already discussed, EMI shielding works through either reflection or absorption of electromagnetic radiation, to provide protection to the instruments/electronics from the source of radiation. The versatile nature and intrinsic properties of carbon materials such as high electrical conductivity, high surface area, chemical and thermal stability have made them an efficient candidate for EMI shielding applications. Additionally, their low density is advantageous in the development of lightweight EMI shielding materials. Carbon based composite materials have been developed to improve the EMI shielding and other important properties such as flexibility, mechanical, dielectric, lifetime etc. Graphite, carbon black, carbon fibers/carbon nanofibers, carbon nanotubes, graphene/graphene oxide etc., are different carbon materials extensively used for advanced EMI shielding applications.

Graphite

Graphite has good electrical conductivity and high surface area which make them an ideal shielding material. Graphite in different forms has been reported for EMI shielding applications. Luo and Chung (Luo, 1996) first time reported the flexible graphite for EMI shielding applications. Exfoliated graphite flakes when compressed without a binder form flexible graphite sheet. Similarly, Bayer *et al.* (2012) fabricated first time the composite of colloidal graphite with Teflon for EMI shielding. Colloidal graphite is a suspension of graphite powder in a liquid medium and small amount of a polymeric binder which is conductive and can be used for EMI shielding application. Composite of expanded graphite and novolac phenolic resin (EG-NPR) is also reported for shielding application in X-band (8.2–12.4 GHz) frequency region (Gogoi and Bhattacharyya, 2014). The presence of delocalized π -electrons is responsible for the conduction network within the flakes and π -electrons accumulation at the interface of EG-NPR causes generation of electrical dipolar polarization.

Carbon fibers

Carbon fibers are very strong and lightweight strands of interconnected hexagonal carbon atoms or graphene sheets with about 5–10 μm in diameter. The excellent properties of carbon fibers such as high strength (five times higher than steel), high stiffness (2 times higher than steel), lightweight, chemical and thermal stability and low thermal expansion made them very popular as an ideal material in many industrial applications. Carbon fibers are made by the series of process involving spinning a long strand of fibers, stabilization at low temperature in presence of oxygen followed by carbonization to a very high temperature in absence of oxygen and finally treating the surface and sizing. Generally, polyacrylonitrile (PAN) is used for making turbostratic carbon fibers and mesophase pitches are used for making graphitic carbon fibers. A carbon-matrix composite containing continuous carbon fibers are recently reported as an excellent EMI shielding materials. Carbon fibers composite are the desired choice of materials over the traditional metallic alloys. Nickel and copper coated carbon fibers have been reported in this regard which shows excellent EMI shielding properties. The high electrical conductivity, high aspect ratio, ferromagnetic behavior and small diameter favors absorption of EMI radiations (Lu *et al.*, 1996; Shui and Chung, 2000). Similarly, polymer-based composites with carbon fibers as reinforcement are gaining attention because carbon fibers forms of a conductive network path within the nonconductive polymer matrix and enhances its EMI shielding ability. The conductive network depends on the fibers length and improves if the longer length fibers used. Luo and Chung (1999) compare the EMI shielding abilities of the long length continuous carbon fibers with short carbon fibers and found that former shows higher EMI shielding properties. Likewise, when short carbon fiber was compared at the same concentration with carbon black powder, higher aspect ratio of short carbon fiber provided a better shielding performance than the latter (Sau *et al.*, 1998).

Carbon black

Carbon black is one of the conductive carbon materials extensively employed for improving the conductivity of the polymer matrix. The low cost and conductive nature made it an affordable and accessible EMI shielding material. Carbon black is small carbon particle formed by thermal decomposition of hydrocarbons in the gaseous phase (Sichel, 1982). Das *et al.* (2000) reported the EMI shielding performance of carbon black and natural rubber/ethylene vinyl acetate copolymer and observed good EMI shielding properties due to voids present in the conductive framework which causes uneven variation in the reflection loss. In another study, the impact of particles contacts on conductivity and therefore the EMI shielding property was studied. Oh *et al.* developed the multilayer carbon black reinforced composites with glass and epoxy as radar absorbing materials (Oh *et al.*, 2004). Carbon black within a matrix of polypropylene has also been evaluated as an EMI shielding material by Al-Saleh and Sundararaj

(2012). They reported that uniform dispersion and distribution of the filler in the matrix play an important role in EMI shielding properties. Moreover, the parameters such as filler structure and conductivity define composite behavior, i.e., reflection or absorption.

Carbon nanotubes

The EMI shielding performance of the composites mainly depends on reinforcing material's intrinsic conductivity, aspect ratio, dielectric constant and size etc. Low density, high aspect ratio, small diameter and high electrical conductivity of carbon nanotubes have attracted interest of scientific community for developing lightweight, flexible, and electrically conductive composites with high electromagnetic interference (EMI) shielding effectiveness. High strength and/or multifunctional composites can be prepared when carbon nanotubes are used as reinforcement into metals, polymers and ceramics matrix. CNT have higher strength but lower density than carbon fibers. The high strength can be used in development of polymer/CNTs nanocomposite parts for aerospace and other high-performance applications required low loading and low density to replace commercial carbon fibers composites. In addition, CNT shows both elastic and plastic distortion behavior which can be used to relieve stresses. These properties make them soft when used in low loading but stiffer on higher loading hence can withstand large deformations without breaking. Also, it makes them an outstanding toughening nanofillers for polymer composite because this behavior is not shown by graphite fibers. Moreover, aspect ratios of CNT are higher (approximately 10,000) than other carbon fillers, thus CNT shows better electrical conductivity and mechanical properties in nanocomposite as reinforcement material (Gupta *et al.*, 2013b). The high aspect ratio and high surface area of CNTs aids in better interaction within a matrix CNTs than that of carbon fibers. Consequently, the lower CNT loading can significantly improve the mechanical strength and electrical conductivity of composites especially of polymer nanocomposite. For example, MWCNT have been used as reinforcement in polystyrene matrix and tested in the frequency range of 8.2–12.4 GHz (X band) (Yang *et al.*, 2005a). Similarly, Kim *et al.* reported the effect on electrical conductivity and EMI properties when MWCNT were used as conductive reinforcement in iron (Fe) doped poly-methyl methacrylate (PMMA) (Kim *et al.*, 2004). The presence of Fe in the composite support the electrical conductivity, charge tunneling in the composite and electromagnetic radiation absorption. Liu *et al.* prepared a layered composite of iron oxide (Fe_3O_4) and Fe incorporated MWCNT dispersed in the matrix of epoxy polymer (Liu *et al.*, 2014). Absorption dominated EMI shielding was achieved for tri-layer composite in the frequency range of 3.22–40 GHz. Similarly, core shell nanostructures ($\text{Fe}@\text{Fe}_3\text{O}_4$) decorated CNT was dispersed in a matrix of polypropylene grafted maleic anhydride (He *et al.*, 2014). Xiang *et al.* studied the EMI shielding properties of MWNT and silica composite (Xiang *et al.*, 2005). A layered composite of MWCNT in polycarbonate matrix was investigated by the Shailaja *et al.* in the X band (Pande *et al.*, 2014). Liu *et al.* reported the preparation of CNT reinforced carbon fibers/pyrolytic carbon (PyC) composites and observed that the CNT grafted in-situ made a conductive network into the pores and gaps present in the composite, thereby improving the conductivity and EMI shielding prepared CNT-C/C composites (Mei *et al.*, 2015).

Liu *et al.* reported the composite of single walled CNT dispersed in polyurethane matrix (Liu *et al.*, 2007). Huang *et al.* further continued the study by using long, short and annealed SMCNT in polymer matrix and found that in long length SWCNT the conductive network was obtained at lower loading compared to short and annealed SWCNT (Huang *et al.*, 2007). Hence, long length SWCNT shows better EMI shielding properties compared short and annealed ones. As percolation threshold for CNT is attained at very low loading. Therefore, CNT in low loading can enhance certain aspects of the composite without affecting the properties of the host matrix material and can be used for lightweight EMI shielding application especially in military and aerospace industries. Polymer matrix composites of CNT with polymers such as polyacrylate, Polyaniline (PANI), poly vinyl alcohol, acrylonitrile–butadiene–styrene, poly-tri-methylene-terephthalate, were also developed in an effort to achieved better EMI shielding properties.

Zhan *et al.* reported the natural rubber/carbon nanotubes (F-NR/CNTs) composite foams through facile latex mixing processes, i.e., rubber crosslinking and ScCO_2 foaming with excellent electromagnetic interference (EMI) performance (Zhan *et al.*, 2019). Due to the porous interconnected morphology, F-NR/CNTs possess low density, good electrical conductivity and high mechanical properties. The porous architecture results in multiple radiation reflections and scattering phenomena in between the cell matrix boundaries which leads to excellent specific shielding effectiveness of $312.69 \text{ dB cm}^2 \text{ g}^{-1}$ for F-NR/CNTs. Wang *et al.* reported the hierarchical composite of multiwall carbon nanotube (MWCNT)- $\text{Fe}_3\text{O}_4@\text{Ag}$ prepared from acylamine reaction between amino functionalized MWCNTs (MWCNTs-NH₂) and carboxylation of $\text{Fe}_3\text{O}_4@\text{Ag}$ ($\text{Fe}_3\text{O}_4@\text{Ag}-\text{COOH}$) nanoparticles (Wang *et al.*, 2019a). The work described the EMI SE of 35 dB with outstanding Young's modulus of 4.60 GPa (hardness = 0.26 GPa) and excellent thermal stability (183.4°C). The incorporation of $\text{Fe}_3\text{O}_4@\text{Ag}$ nanoparticles enhanced formation of conductive networks and offered more interfaces to reflect and reabsorb EM waves, results in improved EM wave's absorption.

Guo-Ming Weng and coworkers used unique combinations of nanostructured materials and polymers through spin spray layer-by-layer (SSLbL) to assemble $\text{Ti}_3\text{C}_2\text{Tx}$ MXene-carbon nanotube (CNT) composite films (Weng *et al.*, 2018). It is shown that semi-transparent LbL MXene-CNT composite films possess high flexibility and stability required for next generation EMI shielding applications. They used poly(vinyl alcohol) (PVA) and poly(sodium 4-styrene sulfonate) (PSS), as the key fillers for SSLbL films and reported high conductivity up to 130 S cm^{-1} with a high specific shielding effectiveness SSE/t of $58,187 \text{ dB cm}^2 \text{ g}^{-1}$, which is credited to both the improved absorption with the SSLbL design of the film and the brilliant electrical conductivity of the conductive fillers (i.e., MXene and CNT).

Graphene/graphene oxide

Graphene is 2D nanomaterial arranged sp² reinforced carbon molecules that are connected with each other in a hexagonal lattice structure. Among all the carbon-based nanomaterials graphene is found to have interesting properties, for example, high electrical

Table 2 A comparison of electromagnetic interference shielding effectiveness of different polymer based composite materials reported in literature

Material	Method	Filler loading	Thickness (mm)	EMI shielding (dB)	Electrical conductivity ($S\ cm^{-1}$)
PMMA/rGO nanocomposite (Sharif <i>et al.</i> , 2017)	Emulsifier-free emulsion polymerization	2.6 vol% rGO	2.9	63.2	91.2
EG/Polyamide 6 (PA6) composite (Duan <i>et al.</i> , 2018)	Mechanical mixing and hot pressing	2.27 vol% EG	2	25	0.55
Natural wood/Epoxy wood-derived carbon scaffolds (Shen and Feng, 2019)	Vacuum-assisted infiltration of epoxy into carbon scaffolds	7.0 vol% carbon	2	27.8	12.5
PDMS/rGO/SWCNT composite (Zhao <i>et al.</i> , 2018)	Solgel followed by backfilling approach	0.28 wt%	2	31	1.2
Fe ₃ O ₄ /TAGA/Epoxy nanocomposites (Huangfu <i>et al.</i> , 2019)	Thermal annealing	1.5/1.2 wt% Fe ₃ O ₄ /TAGA	3	35	27.5
PEDOT/rGO/SrFe ₁₂ O ₁₉ nanocomposites (Dalal <i>et al.</i> , 2019)	Emulsion polymerization	1:0.5:2.2	2.5	42.29	–
RGO/LDC aerogel (Zeng <i>et al.</i> , 2018)	Freeze-drying followed by carbonization	1:1	9.46	49.2	4.99

conductivity ($\approx 6000\ S/cm$), excellent mechanical strength ($\sim 1\ TPa$), large surface area ($2630\ m^2/g$) and high thermal conductivity ($\approx 5000\ W/m/K$). These appealing properties make it an amazing material for number of advanced applications, for example sensors, optoelectronics, energy storage, EMI shielding, biomedicine, and so on (Lee *et al.*, 2017a; Song *et al.*, 2014). EMI shielding of monolayer graphene is first time investigated by the Hong *et al.* (2012). They utilized polyethylene terephthalate (PET) film to move the monolayer graphene developed through chemical vapor deposition technique to study EMI properties. It is observed that monolayer graphene can block 40% of the electromagnetic radiation incident on it and EMI SE value increases linearly with increase in no. of graphene layers. The outcomes also demonstrate that monolayer graphene shows far more superior shielding performance than gold film of 10 nm thickness. Plane-wave hypothesis for metal shield is also applicable to graphene. Zhang *et al.* and Song *et al.* prepared graphene paper for EMI shielding (Song *et al.*, 2014; Zhang *et al.*, 2015a). The graphene paper shows high electrical conductivity of $233\text{--}680\ S\ cm^{-1}$ which is responsible for high EMI SE of the paper. The outcomes demonstrate graphene paper to be an ideal light weight and flexible material which can be utilized for aerospace applications. Yan *et al.* developed graphene-polystyrene composite for EMI shielding (Yan *et al.*, 2012). Chen's *et al.* prepared composites paper of iron oxide nanoparticles containing graphene oxide (GO) using an ordinary GO and thermally treated GO respectively (Chen *et al.*, 2015).

Kong *et al.* reported reduced GO (RGO) sheet containing clusters of $\gamma\text{-Fe}_2\text{O}_3$ colloidal nanoparticle (Kong *et al.*, 2013). The magnetic nanoparticles induced interfacial polarization and decrease in conductivity of reduced GO results in the absorption-dominant EMI shielding. Similarly, composite film of RGO/ $\gamma\text{-Fe}_2\text{O}_3$ /carbon fibers have also been reported (Singh *et al.*, 2012). In another study RGO-ferrofluid incorporated cement is used for investigating EMI shielding ability and results shows that strong polarization effect and magnetic loss properties of ferrofluid helped in achieving good shielding behavior (Singh *et al.*, 2011b). Similarly, $\gamma\text{-Fe}_2\text{O}_3$ decorated, RGO-PANI core-shell tubes structure have been used (Singh *et al.*, 2014). The high surface area, interfacial polarization, magnetic loss and defects formed during preparation of the hybrid composite contributes to the EMI shielding values. Sun *et al.* prepared laminated magnetic graphene using solvothermal method for EMI shielding studies (Sun *et al.*, 2013). Tung *et al.* developed a hybrid composite of Fe_2O_3 -decorated RGO and poly-3,4- ethylene di-oxy thiophene (PEDOT) (Tung *et al.*, 2012). Similarly, there are several reports of composites graphene/graphene oxide with epoxy, BaTiO₃ decorated GO graphene/graphene oxide with phenolic resins, polyurethane, poly-(ethylene oxide) (PEO), PMMA and so on (Singh *et al.*, 2012; Liang *et al.*, 2009; Hsiao *et al.*, 2013; Bai *et al.*, 2011; Zhang *et al.*, 2012).

Recently, Wang *et al.* introduced the concept of green EMI shielding using eco-mimetic 3D nanoarchitecture of Graphene/carbon/polyurethane (GCP) for green EMI shielding and obtained SE up to $\sim 54\ dB$ and outstanding green index (gs) of ~ 1.44 (Wang *et al.*, 2019b). Green shielding index (gs) is a new factor introduced in this study to evaluate environment friendliness. They reported that the unique 3-D structure in eco-mimetic nanoarchitecture results in stronger conduction loss. The honeycomb like surface is related to wedges, producing comparable wedge effect, leads to downward reflection of incident waves and suppressing secondary reflection. Furthermore, its porous structure causes multiple reflection and scattering phenomena which traps EM wave and its hierarchical structure gives more polarization centers, producing more dipoles that absorb electromagnetic energy.

Similarly, Zhang *et al.* reported the WS₂-rGO architecture for green EMI shielding and successfully achieved shielding efficiency (SE) over 32 dB in the frequency range of 2–18 GHz with an endearing green index (gs ≈ 1.0) (Zhang *et al.*, 2019). The effective green EMI SE is attributed to the staggered structure and natural dielectric properties of the WS₂ – rGO framework, including the supportive relaxation and conduction, multiple internal-scattering between the interface and void, and the comparable wedge impact.

Table 3 A comparison of electromagnetic interference shielding effectiveness of different composite materials reported in literature

Composites	Density (g/cm ⁻³)	Thickness (mm)	Frequency (GHz)	EMI SE (dB)	Specific EMI SE (dB cm ³ /g)
Carbon foam-MWCNT (Kumar <i>et al.</i> , 2013a)	0.54	2.75	8.2–12.4	85	163
Graphene-PMMA composites (Zhang <i>et al.</i> , 2011)	0.79	2.4	8.2–12.4	19	25
CNT-PS Composite Foam (Yang <i>et al.</i> , 2005a)	0.56	–	8.2–12.4	19	33
Polyimide-Graphene composite foam (Li <i>et al.</i> , 2015)	0.28	0.8	8.2–12.4	21	75
Fe ₃ O ₄ -Graphene paper (Song <i>et al.</i> , 2015b)	0.78	0.3	8.2–12.4	24	31
Fe ₃ O ₄ -RGO-PEI Composite foam (Shen <i>et al.</i> , 2013)	0.40	2.5	8.2–12.4	18	45
MCMB-MWCNT-Fe ₃ O ₄ composite paper (Chaudhary <i>et al.</i> , 2017)	0.5	0.48	8.2–12.4	80	160
PS-Graphene composite (Yan <i>et al.</i> , 2012)	0.45	2.5	8.2–12.4	29	65
PDMS-Graphene foam (Chen <i>et al.</i> , 2013)	0.06	1.0	8.2–12.4	20	333
MCMB-Fe ₃ O ₄ composite (Dhawan <i>et al.</i> , 2015)	1.6	2.5	8.2–12.4	75	47

LCP-MWCNT (Yang <i>et al.</i> , 2005b)	1.3	1	1	60	46

Graphene nanoribbon and other miscellaneous forms

Graphene nanoribbons (GNR) are strips of graphene showing different behavior compared to its parent structure. The normal width of GNR is observed to be 12–20 nm in various regions while in case of unzipped CNT, ranges from 6 to 10 nm. Fujita *et al.* introduced the theoretical model of graphene ribbons in order to investigate the edge-dependent properties and nanoscale size effect in graphene structure. There are generally two types of edge states in GNR, zigzag and armchair that can be seen on the top portion of the side wall. GNR as graphene strips or unzipped CNT structure is a quasi 1D structure. The electronic structure of GNR is not the same as those of 2D graphene and depends on the edge states. GNR, formed through the longitudinal unzipping of CNT, are most appropriate fillers for nanocomposite materials due to their high surface area (Celis *et al.*, 2016). Composites of graphene nanoribbons have been developed and reported for energy storage, transistors, high strength materials and EMI shielding applications. Joshi *et al.* reported the GNR/PVA composite films by means of solvent casting technique and demonstrated its EMI SE at varying films thickness and GNR concentration of 0.75, 1.5 and 2.5 wt% in X-band. GNR/PVA composites of 2.5 wt% shows the highest EMI SE value at 0.6 mm thickness. In this way, these results proved the effectiveness of these types of composites in a paint that can be coated over the electronic gadgets so as to obtain excellent EMI shielding performance (Joshi *et al.*, 2013). Gupta *et al.* developed MnO₂ decorated GNR, for EMI shielding studies in Ku band frequencies (Gupta *et al.*, 2014). The MnO₂ decoration over GNR improves anisotropy energy, interfacial and electronic polarization. Similarly, Joshi *et al.* blended GNR/PANI/epoxy composites with thickness of 1.7 mm and 3.4 mm and the absorption dominated EMI SE was observed in the X band at 2.5–5 wt% concentrations of GNR (Joshi *et al.*, 2015). The developed composite shows its usefulness for advanced EMI shielding applications especially in aerospace industries because of high strength and excellent EMI shielding properties (Tables 2 and 3).

Besides the above-mentioned types of carbon composites, highly complex composites have been developed in order to meet demands of improved EMI shielding performances for advanced electronic devices. In this regard, Composites of SiCf/SiC have been developed with varying thicknesses of pyrolytic carbon interphase (Ding *et al.*, 2013). Kumar *et al.* prepared the composites of carbon foam decorated with MWCNT and nanosized iron particles and found that MWCNT carbon foam shows the excellent shielding performance (Kumar *et al.*, 2013a). Similarly, composites of CNT polystyrene foam (Yang *et al.*, 2005a), CNT buckypaper (Park *et al.*, 2009), sandwiched composite of carbon texture and epoxy (Kim *et al.*, 2014), silicone foam loaded with carbon nanotubes and functionalized graphene etc are some of the novel composite structures examined (Verdejo *et al.*, 2008).

Reinforcement With Conductive Fillers

Reinforcements or fillers are specific fibers, or fabrics used to modify or enhance properties of the matrix materials such as friction, wear resistance, electrical and thermal conductivity, flame resistance etc. Reinforcements or fillers changes the properties and structure of the materials to which they are added. They toughen or strengthen the metals, plastic or ceramics-based matrix. Generally, they are used to modify and enhance the physical and mechanical characteristics of the plastics for example electrical conductivity of the plastics gets improved when a conductive filler is added to it and consequently EMI shielding performance is improved. The conductive fillers are extensively reported for improving the electrical conductivity of the polymeric composites. Reinforcements may also lower the cost of the material by reducing the required matrix resin volume. The simplicity of processability and lightweight of fillers make them more appropriate as EMI shielding material in the composite. These conducting fillers composites have been designed typically on the basis of the filler concentration, electrical conductivity, aspect ratio and structure

of filler orientation. Different types of reinforcing materials most commonly used are the carbon fibers, nickel-plated carbon fibers, conductive paint spray and metallic mesh etc.

For achieving higher levels of shielding, a layer of conductive filler mainly metal is added to the material through the following approaches:

- (1) Foil bonded to the composite.
- (2) Copper mesh injection molded onto the composite.
- (3) Electroplated with a thin layer of copper over a nickel underplating.
- (4) Metal meshes.

Foil Bonded to the Composite

A thin foil of metal bridging two adjacent laminates is used to provide conductive pathway for flow electrons from one sheet to another. Metal foil primarily made of aluminum and copper. Initially, aluminum was one of the first choices due to its lightweight but the danger of galvanic erosion in contact with carbon fibers was the major concern and an isolation with ply of fiberglass added the extra weight to the structure. Additionally, if moisture enters the composite surface, corrosion of aluminum can occur. Copper eliminates the chances of galvanic reaction risk, but its high density, twice as much as aluminum, create again a problem. Furthermore, foils are less popular for EMI shielding enclosures and other precision shapes due to the problem of conforming the foil to the enclosures shape. To overcome the extra weight, researchers have investigated new multifunctional approaches, for example conductive paint spray and a low-resistance structural laminate etc.

Recently Zong *et al.* reported the solution-based system to prepared a large-area foil of hybrid TaS₂/organic superlattice TaS₂[hexylamine]_x[N-methylformamide]_y (TaS₂HA_{0.371}NMF_{0.135}) where organic molecules and TaS₂ monolayers are alternatively stack at atomic scale (Zong *et al.*, 2019). The hybrid foil fabricated shows outstanding mechanical flexibility together with high electrical conductivity of $1.2 \times 10^3 \text{ S cm}^{-1}$ and an electromagnetic shielding effectiveness value of 31 dB.

Yener *et al.* reported the Ni–NiAl₃ multilayer composites fabricated by using Ni and Al foils through reactive sintering in an open environment with an initial thickness of 250-μm (Yener *et al.*, 2016). The as prepared composite displays more than 50 dB EMI SE in wide frequency range (from a few GHz to over 18 GHz). Similarly, hybrid composites of characteristic natural fiber mats, aluminum sheets and epoxy resin, were developed through vacuum assisted resin transfer molding (VARTM) technique (Xia *et al.*, 2017). In the reported work, EMI shielding efficiency, flexibility, tensile strength and interior bonding characteristics of the hybrid composites were analyzed. Hybrid composites offered fantastic EMI shielding performance with good mechanical properties acquired from aluminum sheets and natural fiber-based composites, separately. Similarly, composites of stainless steel fiber (SSF)/CNTs (Shajari *et al.*, 2019), 3D Cu/Ag shell network composites (Lee *et al.*, 2019), composites of polyethylene filled with polyamide particles coated with silver (Krupa *et al.*, 2007), Ferro-Aluminum based sandwich composite (Ma *et al.*, 2016) etc., are also reported in the literature for their EMI shielding properties.

Copper Mesh Injection Molded Onto the Composite

Copper mesh has been customarily utilized on airframe structures for providing protection against EMI and lightning. Composite enclosure is covered by the copper mesh which can be injection molded onto a composite surface and offers phenomenal EMI protection of – 80 dB up to 25 GHz. The main challenge of using this method is the complete casing of whole complex structure of the enclosures.

Electroplated With a Thin Layer of Copper Over a Nickel Underplating

Copper is an excellent electrical conductor; hence copper plating is extensively used for shielding purpose in electromagnetic and radio frequency interference. In the electroplating process, a very thin layer of copper is deposited over the base metal using a strong electric field. A strong bond is made up by mechanically/chemically formulating the underlying surface of the composite. However, base metal such as iron required a nickel-based coating as passivated surfaces cannot be properly coated by the copper. Copper plating is a simple and really effective way of metal finish and therefore more popular among the concerned industries.

Copper has advantages such as high electrical conductivity and hence a very thin layer can show excellent shielding performances. Additionally, copper is soft and flexible and can be easily used for electrical parts where flexibility is the prime requirement. Furthermore, copper provide uniform surface coating which stick to the surface even on bending the surface and never shells out. Moreover, copper plating provide protection to the other metals from corrosion as it is less corrosive compared to other metals.

Metal Meshes

The acknowledgment of EMI shielding in the optoelectronic devices, particularly for optical windows or vaults, is yet a challenging task. High optical transparency and excellent EMI shielding performances are the two fundamental requirements that drive the advancement in transparent EMI shielding materials for various applications. Furthermore, under extreme situations, broadband

transmission range transparent EMI shielding materials with stable imaging quality are important for a wide range of civil, military and aviation applications (Hu *et al.*, 2012; Han *et al.*, 2015; Tan and Lu, 2007; Batrakov *et al.*, 2014). The development of the excellent EMI shielding material with all its desirable properties remains a tough innovative challenge. For high demands of shielding effectiveness with visual transparency in display windows, metal meshes are developed that display absolutely uniform black coloration and good damping values. Metal-meshes with submillimetre grade spacing and micron size linewidth are the ideal materials for high-performance transparent EMI shielding applications (Han *et al.*, 2016; Lu *et al.*, 2014). These structures show special optoelectronic characteristics, different from the trade-off relationship of conventional conductive EMI shielding materials. Conductivity of metal-meshes can be tuned through their thickness without influencing the transmittance. Accordingly, metal-meshes can be made on various substrates to fit optical transmission and EMI shielding prerequisites. A variety of wire meshes made of copper or bronze are developed for shielding electromagnetic radiations in rooms and non-optical structures. Besides this, copper, nickel and stainless steel (ferritic stainless steel) wire mesh with other composites materials are most commonly used for EMI shielding applications. Recently hybrid shielding materials composed of metal mesh or metal wires and graphene have shown tremendous potential because of their optoelectronic properties (Zhu *et al.*, 2011; Kholmanov *et al.*, 2012; Lee *et al.*, 2013; Gao *et al.*, 2015; An *et al.*, 2014; Dong *et al.*, 2014). In this regards, single-layer graphene has showed perfect shield for metals from mechanical or chemical damages (Das *et al.*, 2015; Kim *et al.*, 2016). Interestingly, the hybrid film containing highly conductive metallic mesh and monolayer graphene exhibited slight enhancement in conductivity compared to the corresponding metallic mesh only (Han *et al.*, 2017). The dominant shielding mechanism of the monolayer graphene is absorption, while that of metal meshes is reflection. Consequently, the hybrid film would be more efficient in its EMI shielding performance, due to the improvement in both reflection and absorption caused by the conductivity enhancement brought by the graphene.

EMI Characterization Methods

To measure the EMI shielding of materials, technically correct testing methods have to be developed and applied in the correct ways to ensure accurate calculations of the shielding effectiveness value. There are four different ways to calculate the EMI shielding effectiveness of a given shielding material:

- (1) Open Field or Free Space Method.
- (2) Shielded Box Method.
- (3) Shielded Room Method.
- (4) Coaxial Transmission Line Method.

Open Field Method

The open field or free space method is a technique used to estimate the shielding effectiveness of a complete electronic setup and can measure the radiations that escape from a complete assembly (Wilson *et al.*, 1988). Although, this method is unable to measure the performance of individual material but can be subject to wide frequency measurements around tens of GHz upper frequency limit. Moreover, shielding effectiveness of large size samples can be possible. Additionally, in-situ measurements are also possible and hence this test is a type of service performance for the design of complete electronic assembly.

The free space method uses certain frequency transmitting antenna for measurement depending on the required type of data (reflection or transmission values). The free space method involves placing the device at a 30 m distance from a receiving antenna and recording the electromagnetic radiation or conducted emissions transmitted down the power line. The main problems of these techniques are those associated with separation of the desired electric field from disturbing fields.

Shielded Box Method

This method is applicable for comparative measurements of samples of varying shield materials. The setup consists of a metal box and an electrically tight seam with a sample port in one wall and a receiving antenna. Also, a transmitting antenna is fitted outside the box. The antenna received the signal and its intensity is recorded by the open port and with a test specimen fitted over the port. The main disadvantages of this method are to maintain a suitable electrical contact among the shielded box and test specimens. The other problem is limited frequency range (500 MHz).

Shielded Room Method

The method is the most accurate method and has been established to overcome the limitations of shielded box method. Although, general working principle of method is the same as the shielded box method but components of the measuring system are isolated in separate rooms, for examples signal generator, transmitting and receiving antennas and recorder are confined separately to eliminate the chances of unexpected interference. Additionally, the antennas are placed in anechoic chambers of room size with large size specimen up to 2.5 m² in area capacity. As compared with the shielded box method, in this method range of the frequency and reproducibility of the data is enhanced over which consistent results can be obtained.

Coaxial Transmission Line Method

The coaxial transmission line method is the most preferred method for the measurement of shielding effectiveness in the controlled medium (Sarto and Tamburrano, 2006; Hong *et al.*, 2003). The setup consists of a holder transmission line with a vector network analyzer (VNA). The test sample is placed in coaxial transmission line holder and measured the reflection coefficient (S_{11}) and transmission coefficient (S_{22}). By measuring these scattering parameters absorption and reflection contribution to the total shielding effectiveness is determined as mentioned earlier using the Eqs. (6) and (8). The S-parameters demonstrates a 2-port network response to voltage signals generated and received at each port. The major advantage of this method is that the outcomes of different laboratories are analogous. Additionally, the coaxial transmission line can resolve the data into different components namely reflected, absorbed and transmitted. Test sample are small doughnut shaped and measurements can be performed at specific frequencies by means of a modulated signal generator, crystal detector and amplifier. Standard coaxial cables can measure a dynamic range of about 80 dB.

Summary

This article is built upon a literature study with the aims to provide the reader with a basic understanding related to the topic of EMI shielding materials and suggesting their possible explanations. In addition, a general literature review of EMI shielding techniques and its theory is presented in this article. Although various techniques and significant work have been done to make various kinds of composites materials for EMI shielding, still researchers are working in this field to accomplish better capabilities containing materials for advanced EMI shielding applications. The fundamental issues on which major work focused is the composites of lightweight shielding materials such as polymers, foams and aerogels composites but composites containing carbon nanostructures reinforcement are attracting major research interest of scientific community. Generally, composites are made at lab level and tested. It is significant to deal with the synthesis mechanism which can be scaled up and can be really utilized at industrial level. Other issues such as EMI shielding range over which the materials work as shielding materials required attentions. Endeavors are expected to improve the required composites to provide EMI shielding at various frequencies. There is additionally a requirement for understanding the instrument and mechanism of shielding in case of carbon nanostructures. More efforts are required to maintain the testing conditions for better reproducibility of EMI shielding performances.

Corrosion Characteristics of Metal Matrix Composites

Devadas Bhat Panemangalore and Udaya Bhat K., Department of Metallurgical and Materials Engineering, National Institute of Technology Karnataka, Surathkal, Srinivasnagar, Karnataka, India

Introduction to MMCs

Definition

To obtain enhanced properties than either of the individual materials, metal matrix composites (MMCs) have evolved over the past few decades with several distinct advantages. MMCs consist of an embedded reinforcing phase that can be continuous or discontinuous in a metal matrix. The development of MMCs started in the 1950 s and several new materials are synthesized in the laboratory even today targeting various custom-made, commercial applications.

Types of Composites

Depending on the requirement of mechanical, thermal, corrosion resistance properties, etc., the material selection including matrix and reinforcement is carried out. The most common matrices include aluminum (Verma *et al.*, 2015), magnesium (Lei *et al.*, 2012), iron (Wu *et al.*, 2020), copper (Jin *et al.*, 2019), titanium (Hayat *et al.*, 2019), nickel (Munday *et al.*, 2020), nickel aluminides (Talaş and Oruç, 2020), nickel-based superalloys (Chen *et al.*, 2020) and zinc (Liu *et al.*, 2020). The reinforcements can be classified based on their aspect ratio into continuous fiber (Jiao *et al.*, 2019), monofilaments (Ward *et al.*, 2002), discontinuous fiber (Behera *et al.*, 2020), whisker (Li *et al.*, 2021), particulate (Gad *et al.*, 2020) and multi-layered laminates (Mo *et al.*, 2020). MMCs can be synthesized either by powder metallurgy route (Venkatesh and Deoghare, 2020) or via casting route (Srinivasan *et al.*, 2020). Nowadays, for structural, automotive, and aerospace applications, light metal matrix composites are also gaining importance that comprises of a light (Al, Ti, Mg) metal matrix incorporated with a reinforcement that can improve the mechanical properties and wear resistance (Jayalakshmi and Gupta, 2015). For jet engine turbines, high-temperature refractory metal-intermetallic composites that can provide enhanced toughness, oxidation, and rupture behavior have become a competitive choice of material (Jackson *et al.*, 1996).

Physical and Mechanical Properties

The reinforcements play a major role in the mechanical properties such as elastic modulus and fracture toughness of the composites, some of which depend on their interaction and orientation concerning the matrix. Physical properties such as density, specific heat, thermal conductivity, and thermal expansion coefficient values depend on the intrinsic properties of the materials. Reinforcement/matrix interface plays a vital role in the development of composites with enhanced properties. The production technologies also play a major role in developing the property profiles of metal matrix composites.

Corrosion Properties

Due to the different electrochemical behavior of the matrix and reinforcement, the MMCs are prone to galvanic corrosion. Reinforcement phases can also lead to discontinuities in the protective passive film, leading to poor corrosion resistance (Pardo *et al.*, 2005). However, with careful selection of materials, processing techniques and tailoring the microstructure, it is possible to design MMCs with enhanced corrosion resistance. The electrochemical behavior and degree of corrosion also depend on the type of environment in which the material is tested and the electrochemistry of the reinforcement. Several review articles have been published in this domain. Hihara *et al.* (Hihara and Bakkar, 2016) reviewed corrosion of metal matrix composites and listed out the electrochemical effects of the interfaces, chemical degradation, secondary effects, and measuring techniques. de la Fuente reviewed corrosion of aluminum, its alloys, and composites (de la Fuente, 2020). Ali *et al.* (2019) reviewed the corrosion properties of magnesium-based composites for medical applications. Gupta *et al.* (Gupta and Meenashisundaram, 2015) provided an insight into the processing, mechanical, and corrosion characteristics of biocompatible magnesium composites, with an emphasis on the nanocomposites. Shahin *et al.* (2019) studied the corrosion and biological perspectives of Mg nanocomposites focused on orthopedic applications. Rohatgi *et al.* (2017) reviewed the aqueous corrosion of MMCs. Uhlig's Corrosion Handbook (Revie, 2011) is an invaluable resource that covers almost all the aspects of the basics of corrosion, its detection, protection, and testing of both metals and non-metals. In the next section, several types of corrosion have been discussed.

Types of Corrosion

Several types of corrosion have been identified, some of which are localized corrosion (crevice, pitting), galvanic, flow-induced, erosion-corrosion, etc. Corrosion can also occur due to processing conditions, at high temperatures, due to interphase degradation, changes in

the microstructure, and the influence of the environment. Several critical reactions taking place during corrosion that depends on processing conditions, amount of constituents, corrosive environment (electrochemistry), characteristics of metal (metallurgy), etc. together formulates the corrosion mechanism. Based on a plethora of experimental data, a set of standard guidelines published by the American Society for Testing and Materials (ASTM) can help us to understand the corrosion failure analysis of our sample.

Localized Corrosion of MMCs

Unlike general corrosion that takes place uniformly on the entire surface, localized corrosion (Frankel and Sridhar, 2008) is an accelerated attack that involves several mechanisms such as pitting (Frankel, 1998), crevice corrosion at the matrix-reinforcement interface, exfoliation, etc. The SiC influence on the pitting behavior of AA1050 was studied by Trowsdale *et al.* (Trowsdale *et al.*, 1996). They suggested that due to the insulating behavior of SiC particles, galvanic corrosion did not get induced. Larger (20 μm) SiC particles caused enhanced localized corrosion in comparison with smaller (3 μm) particles.

Feng *et al.* (1998) studied the pitting behavior of particulate SiC reinforced AA2024 MMCs and observed localized micropitting at OCPs lower than the pitting potential, E_p .

Ding *et al.* (Ding and Hihara, 2005) observed the formation of microcrevices in B_4C , SiC and Al_2O_3 reinforced 6092-T6 Al MMCs which led to the localized anodic regions transformed into cathodic.

Lv *et al.* (2020) observed localized corrosion behavior in alumina whiskers reinforced Cu MMCs. The effect of graphite and SiC on the pitting behavior of AA 6061 MMCs was studied by Denise *et al.* (Aylor and Morgan, 1985). The crevices around the interface of SiC-Al formed the preferential sites for pitting, but the penetration depth was shallow as compared to the alloy without reinforcement.

Yao *et al.* (Yao and Zhu, 1998) studied the interfacial preferential dissolution (IPD) of SiCp/Al composites in NaCl solution, which can be wrongly identified as pitting. This mode of corrosion caused enhanced dissolution at SiC clusters and cathodic protection led to the suppression of both pitting and IPD.

Pitting corrosion behavior was also observed for cast SiCp reinforced A3xxx MMCs by Pardo *et al.* (2005) along with the presence of $\text{Al}_2\text{O}_3 \cdot 3 \text{H}_2\text{O}$ on the surface.

Kiourtsidis *et al.* (Kiourtsidis and Skolianos, 1998) studied the corrosion behavior of squeeze-cast SiC reinforced AA2024 composites in aerated NaCl solution. The dendrite cores that are depleted of copper led to pitting and galvanic coupling that took place between the intermetallic Al_2Cu and the α -phase but the galvanic corrosion between SiC and the matrix was not observed.

Xu *et al.* (2017) studied the pitting susceptibility of Ti-based metallic glass matrix composites using a potentiodynamic polarization method in 3.5 wt% NaCl solution. The composites $\text{Ti}_{62}\text{Zr}_{12}\text{V}_{13}\text{Cu}_4\text{Be}_9$ (at%), $\text{Ti}_{58}\text{Zr}_{16}\text{V}_{10}\text{Cu}_4\text{Be}_{12}$, $\text{Ti}_{46}\text{Zr}_{20}\text{V}_{12}\text{Cu}_5\text{Be}_{17}$, and $\text{Ti}_{40}\text{Zr}_{24}\text{V}_{12}\text{Cu}_5\text{Be}_{19}$ were synthesized via arc melting and subjected to corrosion testing. The passivation film collapsed at -0.16 V versus SCE and the Cl^- ion induced pitting, which can be seen in Fig. 1. Among all the composites, the one with greater Ti at% showed better corrosion resistance due to the protective oxide film that is rich in titanium and also due to the low percentage of beryllium, which is an active element.

Galvanic Couple

Galvanic couples can be formed with the matrix being an active metal and the reinforcement that can be noble. The definition of galvanic corrosion also called bimetallic corrosion is when two or more dissimilar metals that are immersed in the same electrolyte, are in electrical contact and exhibit a significant potential difference. But MMCs also undergo galvanic corrosion due to the coupling of an active metal (matrix) with a relatively inert reinforcement such as SiC (Hihara and Latanision, 1994). Reinforcement material such as SiC monofilament in a ZE41 matrix acted as an effective oxygen reduction site, thus leading to increased corrosion rate with an increase in dissolved oxygen, which was not observed in pure Mg as well as ZE41A alloy (Hihara

Reproduced with permission from Xu, K.K., Lan, A.D., Yang, H.J., Han, P.D., Qiao, J. W., 2017. Corrosion behavior and pitting susceptibility of in-situ Ti-based metallic glass matrix composites in 3.5 wt% NaCl solutions. Appl. Surf. Sci. 423, 90–99. Available at: <https://doi.org/10.1016/j.apsusc.2017.06.145>.

Fig. 2 Polarization diagrams depicting galvanic corrosion. Reproduced from Hihara, L.H., Latanision, R.M., 1993. Suppressing galvanic corrosion in graphite/aluminum metal-matrix composites. *Corros. Sci.* 34, 655–665. Available at: [https://doi.org/10.1016/0010-938X\(93\)90278-0](https://doi.org/10.1016/0010-938X(93)90278-0).

and Kondepudi, 1993). The corrosion rate of MMCs can also be determined by the resistivity of the ceramic reinforcement – the greater the resistivity, the minimum is the rate of corrosion (Schneider *et al.*, 2014).

Hwang *et al.* (Hwang and Kim, 2002) studied the galvanic coupling effect on the corrosion of SiC reinforced AA2214. It was found that a large cathodic polarization of the reinforcement was responsible for the lower values of the galvanic current, although the corrosion potential of the composite was higher than the alloy due to the galvanic coupling effect. Using a zero-resistance ammeter, Han *et al.* (2013) studied the galvanic corrosion of structural materials like AA6061 or SS304 with Al-B₄C composites in NaCl and H₃BO₃ solutions.

The galvanic corrosion can be studied using the polarization diagrams, as shown by Hihara *et al.* (Hihara and Latanision, 1993) via the electrical insulation method in Fig. 2. A decrease in ohmic drop between the anode and cathode of the galvanic circuit leads to an increase in the galvanic current and it is maximum with IR drop equals zero, as shown in Fig. 2. IR drop is generally calculated as the product of the resistance of the galvanic circuit times the galvanic current.

Flow Induced Corrosion

Due to the effects of turbulence in the fluid flowing over the surface of the material, the attributed corrosion effect is defined to be flow-induced (Revie, 2011). Practically it can occur at the downstream of pipe joints, orifice plates, etc. that can cause disturbed flow (Revie, 2011). Flores *et al.* (2012) studied the corrosion behavior of Ni- and Fe-based MMCs in different slurry conditions. For Ni-based MMCs, a transition from flow-induced corrosion to an erosion-corrosion process was observed.

Erosion Corrosion

The accelerated mass loss due to the combined effect of erosion and corrosion because of the relative motion between the metal and the moving corrosive fluid is erosion-corrosion, which is ubiquitous in soft metals such as aluminum. Aribo *et al.* (2017) studied the erosion-corrosion behavior of snail-shell-ash and SiC reinforced AA6063 MMC in a mono-ethylene glycol (MEG)-water environment. The erosion dominated and the material with the highest hardness was more resistant to degradation. The experiments were conducted using a submerged impinging jet rig as shown in Fig. 3. The miniature rig consisting of a single nozzle is modified from the design developed by Aribo *et al.* using a dual-nozzle arrangement. The reservoir is powered by a water pump, whose speed is controlled by altering the input voltage to the system. The aerated conditions were adapted using mono-ethylene glycol solution with NaCl and weight loss was measured after every experiment.

High-Temperature Corrosion and Oxidation

Due to the chemical reactions taking place between the material and the environment at high temperatures, severe degradation takes place. This is classified into oxidation, hot-corrosion, and sulfidation (Khanna, 2016). Elements such as aluminum, silicon, and chromium can develop adherent, stable, slow-growing, and non-permeable protective oxide scales on the surface (Li and Gao, 2008; Stott, 1992). Geng *et al.* found the improved isothermal oxidation behavior of Nb-Si-Cr-Al in-situ composites with the addition of titanium (Geng *et al.*, 2006). Bewlay *et al.* (2003) reviewed Nb-silicide-based composites for high-temperature applications above 1350°C. Additional oxidation resistance in higher-order silicide-based systems is provided by Laves phases formed by intermetallics, which also improves high-temperature creep properties. These refractory metal-intermetallic composites (RMICs) have the potential to replace Ni-based superalloys shortly.

Fig. 3 Submerged Impinging Jet (SIJ) Rig. Reproduced with permission from Aribio, S., Fakorede, A., Ige, O., Olubambi, P., 2017. Erosion-corrosion behaviour of aluminum alloy 6063 hybrid composite. *Wear* 376–377, 608–614. Available at: <https://doi.org/10.1016/j.wear.2017.01.034>.

Corrosion Experiments and Sample Preparation

In the category of unpolarized-type corrosion experiments (Kirkland *et al.*, 2012), different methods include mass loss, H_2 evolution measurement, and pH monitoring. The former two require multiple samples for testing for accuracy whereas the latter requires pH change during measurement (Kirkland *et al.*, 2012). Witte *et al.* (2007) studied the corrosion behavior of Mg-hydroxyapatite (HAp) using the immersion testing method. Although this is a quick measure of determining corrosion quantitatively, several other aspects to understand the mechanisms cannot be carried out.

Polarized-type electrochemical experiments are commonly used to study the corrosion behavior of MMCs. Bhat Panemangalore *et al.* (2019) studied the corrosion behavior of silica-reinforced magnesium composites in phosphate-buffer saline (PBS) media using potentiodynamic polarization (PDP) tests. These tests provide detail on the instantaneous corrosion rates and the same unpolished sample can be tested for multiple runs (Kirkland *et al.*, 2012). Han *et al.* studied the electrochemical behavior of aluminum reinforced with B_4C composites using electrochemical impedance spectroscopy technique (Han and Chen, 2015). Kiourtsidis *et al.* (1999) used the double cyclic polarization (DCP) method to study the pitting behavior of SiCp reinforced AA2024 composites in NaCl solution. Copper depleted regions in the microstructure served as local anodes that led to greater pitting initiation sites. An increase in SiCp volume fraction did not increase the number of pits. DCP is an accelerated test and Coleman *et al.* (1990) studied the corrosion behavior of carbon/Nicalon/Saffil fiber and SiC particulate reinforcements in two different matrix metals Al-7Si and Al-4Cu in NaCl solution. For open-circuit potential tests, insulated copper wire was used to create electrical contact and epoxy resin was used to mount the specimen.

Linear Polarization Resistance Method

The linear current response generated when a material is polarized by maintaining a small voltage shift (less than 30 mV) near its corrosion potential is used to plot the current-potential curve (Ropital, 2011). The slope of this curve is polarization resistance and this test can be conducted in static/sliding conditions. Stern *et al.* (Stern and Geaby, 1957) provided a theoretical analysis of polarization plots and the polarization resistance (R_p) can be calculated by

$$R_p = \frac{B}{i_{corr}}$$

Where, $B = \frac{\beta_a \beta_c}{2.3(\beta_a + \beta_c)}$, β_a and β_c are the Tafel coefficients and i_{corr} is the corrosion current

Electrochemical Impedance Spectroscopy Including Nyquist Plots

Electrochemical impedance spectroscopy (EIS) uses a common potentiostat to determine the frequency response of the material to an applied AC potential (Cottis, 2010; Stoynev and Vladikova, 2009). Bode and Nyquist plots can be used to understand EIS, where the former consists of a plot between impedance (Z) and phase shift (Φ) versus frequency and the latter, which is more commonly used is the plot between $-Z''$ (negative imaginary impedance) versus Z' (real part).

Microscopic Techniques

Corrosion failures can be examined using scanning electron microscopy coupled with energy-dispersive spectroscopy to identify the damage mechanisms (Pantazopoulos and Vazdirvanidis, 2014). Corrosion initiation can also be studied using an in-situ

Table 1 Corrosion rates of different metal matrix composites in varied corrosive environments

S/No	Material	Corrosive Environment	Corrosion Rate	Type of Corrosion	Reference
1	Al 6013–20SiC (temper T4)	Salt-spray	2.55 mL/y	Erosion-corrosion	(Ahmad and Abdul Aleem, 2002)
2	Al 6013–20SiC (temper F)		3.68 mL/y		
3	Al 6013–20SiC (temper O)		4.27 mL/y		
4	Al-2Mg-SiCp	3.5 wt% NaCl	0.32 mm/year	Pitting	(Candan, 2009)
5	Al-4Mg-SiCp		0.37 mm/year		
6	Al-8Mg-SiCp		0.37 mm/year		
7	Al-5Cu-20SiC	3.5 wt% NaCl	1.78 mpy		(Sivakumar <i>et al.</i> , 2018)
8	Al-5Mg-20SiC		2.69 mpy		
9	MgCa-HA/TCP composite	Hank's solution	0.176 mm/year	Galvanic corrosion	(Gu <i>et al.</i> , 2011)
10	Mg-ZnO	Simulated body fluid	0.25 mgcm ⁻² h ⁻¹	Micro-galvanic corrosion	(Lei <i>et al.</i> , 2012)
11	Mg-6SiC	1 M NaCl	18.1 mm/year		(Tiwari <i>et al.</i> , 2007)
12	Mg-16SiC		45.5 mm/year		
13	AZ92/5 vol% SiC	3.5 wt% NaCl	4.4×10^{-2} mg cm ⁻² h ⁻¹	Localized corrosion	(Pardo <i>et al.</i> , 2009)
14	AZ92/10 vol% SiC		5.6×10^{-2} mg cm ⁻² h ⁻¹		
15	Cu-2.7 vol% Al ₂ O ₃	3.5 wt% NaCl	2.397 mpy	Galvanic corrosion	(Sun and Wheat, 1993)
16	Cu-0.5 wt% Ti ₃ C ₂	9 wt% NaCl solution	1.49 mpy		(Song <i>et al.</i> , 2020)
17	Cu-1 wt% Ti ₃ C ₂		1.80 mpy		
18	Cu-2 wt% Ti ₃ C ₂		2.37 mpy		
19	Cu-2 wt% TiC		1.83 mpy		

atomic force microscopy technique and electrochemical noise techniques (Li *et al.*, 2009). To understand the corrosion mechanisms with high resolution, in-situ transmission electron microscopes can provide an in-depth analysis (Song and Xie, 2018). In-situ observation of the sample subjected to corrosion under a droplet of the corrosive media on the surface can also be analyzed using an optical microscope as a function of time (Ambat *et al.*, 2000). Using in-situ long focal video microscopy and atomic force microscopy, Payan *et al.* (2001) studied the galvanic corrosion aspect of graphite fibers reinforced Al MMCs to get quantitative information, localized study, and 3D morphology.

Corrosion Aspects of Metal Matrix Composites

In this section, corrosion behavior of different metal matrix composites is discussed. Table 1 discusses the corrosion rates of MMCs with respect to their matrix counterpart and the type of corrosion exhibited.

Processing Related Corrosion Problems and Remedies

Paciej *et al.* (Paciej and Agarwala, 1988) studied the influence of processing variables involved in heat treatment and extrusion for a SiCp reinforced AA7091 synthesized using powder metallurgy route. Enhanced corrosion resistance was observed for materials that were processed using a combined effect of modified solution heat treatment and greater extrusion ratio.

Ahmad *et al.* (Ahmad and Abdul Aleem, 1996) implemented numerous age hardening processes to study the corrosion behavior of SiC reinforced Al 6013 MMC. Naturally age-hardened (T4) exhibited enhanced corrosion resistance in comparison with annealed and as-fabricated samples due to the precipitates that are finely and homogeneously distributed in the matrix.

Yue *et al.* (1999) adapted a surface treatment using Nd: YAG laser to enhance the corrosion resistance of SiCp reinforced AA6013 MMC. Resistance to pitting was enhanced and it was attributed to the refinement and removal of Mg₂Si precipitates in the surface. They also enhanced the corrosion resistance of Mg-ZK60/SiC and Al-SiC MMCs using excimer lasers (Yue *et al.*, 1997; Zhang *et al.*, 1996). Yue *et al.* (2002) subjected the SiC reinforced AA2009 composite to different machining conditions and found that the surface finish affects the corrosion behavior. Cemented carbide turning operation exhibited lowest pitting corrosion resistance as compared to wire-electrical discharge machining and single-point diamond turning operations.

Candan *et al.* (Candan, 2009) synthesized pressure infiltrated composites of SiCp reinforced Al-Mg alloy. The intermetallic phases produced lead to the narrowing down or create discontinuities in the matrix thereby results in enhancement of corrosion resistance.

Corrosion of Al MMCs

Graedel, 1989) has reviewed the corrosion mechanisms for aluminum when it is exposed to indoor or outdoor atmosphere, in the presence of humidity, chloride, and sulfide species. Al MMCs reinforced with SiC, and Al₂O₃ have the potential to replace cast iron in engine components in the automotive industry due to their excellent tribological characteristics (Prasad and Asthana, 2004). Al alloys and composites are susceptible to several modes of localized corrosion such as intragranular, stress corrosion cracking (SCC), and

exfoliation (de la Fuente, 2020). In aluminum, the cathodic reaction takes place only at higher current densities and the migration of ions at the oxide film/solution interface is less likely due to the greater electronic resistance of the air-formed oxide film (Pryor and Keir, 1955). Turnbull (1992) reviewed several reinforcements such as SiC, graphite, Al_2O_3 , and B in Al MMCs. Hihara studied the corrosion mechanisms of graphene in Al and SiC in Al MMC in seawater and Na_2SO_4 media (Hihara, 1989). The formation of Al_4C_3 at the interfaces that has a tendency to hydrolyze led to the deterioration of degradation resistance along with the presence of residual microstructural halides that formed during the fabrication process (Hihara, 1989). Among several methods suggested to enhance the corrosion resistance of graphene in Al MMC, cathodic inhibition was effective (Hihara, 1989). SiC and TiB_2 reinforcements led to the reduction of galvanic corrosion rates of Al (Hihara and Latanision, 1992). Similar results were obtained by Griffiths *et al.* after comparing the cathodic current densities of AA6061 and SiC (Griffiths and Turnbull, 1994).

Trzaskoma *et al.* studied the corrosion behavior of SiC reinforced Al MMCs (AA2024, AA6061, and AA5456) (Trzaskoma *et al.*, 1983) in NaCl solution in the presence and absence of dissolved O_2 . The presence of oxygen affects the general corrosion behavior more than the reinforcement and except for AA2024, the pitting susceptibilities of the wrought alloys and composites did not change significantly.

Monticelli *et al.* (1997) studied the stress corrosion cracking behavior of SiCp reinforced AA6061 composites. Various localized corrosion forms were observed and the increase in corrosion rate was attributed to the tensile stress that was detected via electrochemical noise analysis. AA6061 based composites exhibited a lower corrosion rate as compared to AA2014 based composites.

Using salt-spray tests, Ahmad *et al.* (Ahmad and Abdul Aleem, 2002) studied the corrosion behavior of SiC reinforced AA 6013 MMCs and observed the formation of homogeneous protective film boehmite ($\text{AlO} \cdot \text{OH}$) contributing to the reduced corrosion rate at 100°C as compared to 50°C .

Albiter *et al.* (2006) synthesized TiC reinforced Al MMCs via pressureless melt infiltration and studied their corrosion behavior. It was found that the addition of TiC reduced the anodic current density, whereas Cu and Ti-rich particles resulted in galvanic and pitting corrosion.

Deuis *et al.* (1997) developed Al composite coatings containing Al_2O_3 , SiC or TiC synthesized using plasma-transferred arc (PTA) surfacing process on AA5083 and studied their corrosion behavior in 3.5 wt% NaCl solution. The increased volume fraction of Al_2O_3 containing coatings resulted in a lower corrosion rate. SiC and TiC additions enhanced the corrosion rate.

Datta *et al.* (2004) studied the addition of scandium on the corrosion behavior of Al-Si-Mg-SiCp MMCs prepared by the mechanical alloying route. Intermetallic phases such as Al_3Sc and AlSiSc that did not consist of Mg led to the composite containing scandium exhibiting less anodic behavior. Composites without trace additions of Sc revealed intergranular corrosion.

The effect of Cu addition on the corrosion behavior of in-situ developed Mg_2Si reinforced Al-12Si-20Mg matrix composites was studied by Palta *et al.* (2012). The addition of Cu led to form CuAl_2 phase that has a greater positive corrosion potential and led to a reduction in size and volume of Mg_2Si particles which led to an increase in corrosion resistance.

Ding *et al.* (Ding and Hihara, 2019) investigated the galvanic corrosion in B_4C reinforced AA6092 MMCs in Na_2SO_4 solution. Using the zero-resistance ammeter technique, B_4C was identified as cathodic sites that induced galvanic corrosion.

Wielage *et al.* (Wielage and Dörner, 1999) studied the corrosion studies on carbon fibers reinforced Al MMCs, where the reinforcement involved suitable corrosion protection of a pyrolytic carbon or nickel fiber coating. But the coatings did not lead to a significant enhancement in corrosion resistance.

Corrosion of Mg MMCs

Similar to Al MMCs, SiC reinforced Mg MMC also corroded uniformly without micro galvanic corrosion (Nunez-Lopez *et al.*, 1996). The addition of SiC to a ZC71 alloy matrix was studied for its corrosion behavior by Nunez-Lopez *et al.* (Lopez *et al.*, 1995). General corrosion behavior was observed by the composite tested in saline environments, using salt-spray and various electrochemical measurements.

Galvanic corrosion of SiC monofilament coupled to pure Mg and ZE41A was studied by Hihara *et al.* (Hihara and Kondepudi, 1994). Solution oxygenation led to corrosion damage in the galvanic mode as compared to de-aerated solutions, where both local and galvanic corrosion components were comparable.

Ghasali *et al.* (2019) studied the corrosion behavior of Mg- Al_2O_3 and Mg- Si_3N_4 MMCs synthesized using a microwave sintering process. Interfacial reactions led to the inhibition of corrosion and the polarization resistance exhibited was greater than that of pure Mg.

Lei *et al.* (2012) sintered the ball-milled Mg and ZnO powder mixture and obtained in-situ reinforcement of MgO ceramics and Mg-Zn intermetallics that are uniformly distributed which enhances the corrosion resistance of the MMC.

Hydroxyapatite reinforced Mg MMCs were studied for their biodegradability by Witte *et al.* (2007) and they found uniform corrosion behavior in artificial seawater and different cell solutions.

Roseline *et al.* (Roseline and Paramasivam, 2019) used fused zirconia alumina 40 (FZA40) reinforced in AA6061 using the double stir-casting technique. Reinforcements were uniformly distributed and the heat-treated composites showed decreased corrosion current densities tested in H_2SO_4 media even up to 15% reinforcement that acted as a protective layer above the surface of the alloy.

Bakkar *et al.* (Bakkar and Neubert, 2007) studied the role of alumina as a reinforcement on the corrosion resistance of Mg-based matrix. They presented a model to explain the corrosion mechanism and it is shown in Fig. 4. Exposure to oxygen leads to the formation of MgO and Al_2O_3 and it is represented in the figure as Al-containing $\text{MgO}/\text{Mg}(\text{OH})_2$ layer. This surface becomes

Fig. 4 A schematic representative model that shows the corrosion mechanism of alumina reinforced Mg MMC. Reproduced from Bakkar, A., Neubert, V., 2007. Corrosion characterisation of alumina-magnesium metal matrix composites. *Corros. Sci.* 49, 1110–1130. Available at: <https://doi.org/10.1016/j.corsci.2006.07.002>.

Mg(OH)_2 when reacted with an aqueous solution and with time the partially protective Al-containing MgO/Mg(OH)_2 barrier forms that wear due to Cl^- ions which then leads to pitting.

Surfaces rich in aluminum (shown as HA zone in the figure), when exposed to air, forms an initial film made of $\text{Al}_2\text{O}_3/\text{MgO-Mg(OH)}_2$ (shown blue in the figure) and an outer layer made of Al-rich Mg(OH)_2 forms. Corrosion takes place at the matrix as it is anodic compared to surfaces rich in aluminum and it forms severe pits formed via anodic reaction. This progresses with time as Mg^{2+} ions migrate outwards and Cl^- ions diffuse inwards, but the surfaces rich in aluminum are not corroded.

Bakkar *et al.* (Bakkar and Neubert, 2009) also studied the aspect of galvanic corrosion due to the carbon fiber reinforcement on Mg MMCs. Carbon fibers induce crevice corrosion at the interface that was evident in the microstructure of the sample after the polarization test in NaCl alkaline solution as seen in Fig. 5. But pitting was observed for samples subjected to free immersion condition, as seen in Fig. 6.

Falcon *et al.* (2011) studied the corrosion behavior of TiC reinforced Mg-Al composites in NaCl solution and observed that the reinforcement contributed towards resistance towards pitting.

Corrosion of Cu MMCs

Bakkar *et al.* (Bakkar and Ataya, 2014) studied the stainless steel fiber-reinforced copper metal matrix composites in chloride media. Corrosion was initiated at the copper matrix and later pitting of the reinforcement commenced. Microstructural observations post corrosion also confirmed micro galvanic corrosion mechanism.

Jin *et al.* (2019) developed a brick-and-mortar microstructure comprising graphene encapsulated copper nanoflakes as building blocks to synthesize Cu MMCs. The composite exhibited an anisotropic corrosion behavior due to the anti-corrosion effect of graphene as well as the microstructure. A schematic of the anti-corrosion role of graphene is presented as a pathway for corrosion in Fig. 7, emphasizing the role of orientation of the reinforcement in the matrix.

Wang *et al.* (2019) studied the corrosion resistance of graphene reinforced Cu MMCs prepared via powder metallurgy route. Among different compositions, 0.5 wt% graphene content had the lowest corrosion current and highest charge transfer resistance.

Available at: <https://doi.org/10.1016/j.carbon.2018.10.088>.

Song *et al.* (2020) studied the corrosion resistance of Ti_3C_2 reinforced Cu MMCs synthesized via spark plasma sintering technique and the Tafel plots showed the corrosion resistance of the composites greater than Cu.

Graphite and SiC reinforced hybrid Cu MMCs were synthesized by Sadhukhan *et al.* that also exhibited enhanced tribological properties (Sadhukhan and Subbarao, 2020).

Venkatesh *et al.* (Venkatesh and Rao, 2018) studied the corrosion and wear of alumina and graphite-reinforced Cu MMCs. Nano-sized alumina imparted better corrosion resistance to the Cu MMC and graphite provided the lubricating effect.

Ramesh *et al.* synthesized (Ramesh *et al.*, 2009) hybrid Cu-based composites made of a hard reinforcement SiC and soft reinforcement graphite via casting route (vortex method) targeting optimum tribological characteristics. Composites with copper-coated reinforcements also exhibited enhanced wear resistance.

Interfacial Reactions and Their Effect On Corrosion Behavior

Zhou *et al.* (2020) conducted quasi-in-situ TEM studies to understand the structural evolution of the initial stage of corrosion of the B_4C reinforced Al-Mg-Si-Cu composite. They observed the liberated Cu/Mg-rich layer from the interphase boundaries and also the redeposition of Cu clusters on $\text{Mg}(\text{Al})\text{B}_2$ nano-rods that increased the corrosion rate of the composites. A novel technique involving TEM and thermal annealing to study the interfacial reactions in MMCs was devised by Nathan *et al.* (Nathan and Ahearn, 1990).

Effect of Inhibitors

Corrosion inhibitors such as hydrazine reduce the corrosion rate of a material. They are mostly toxic chemicals and therefore there is a need to develop inhibitors that are green and sustainable (Chaubey *et al.*, 2020). Surfactants, due to their amphiphilic nature can also lead to corrosion inhibition (Zhu *et al.*, 2017). Corrosion inhibition using CeCl_3 that suppressed cathodic reactions at the interface of SiC/AA6013 was studied by Ahmad *et al.* (Ahmad and Aleem, 2009).

Conclusions

There are several aspects involved in determining the corrosion behavior of metal matrix composites, especially when there are different reinforcements, intermetallics, and their distribution, reaction with the environment, and the difference in their electrochemical potential values. The presence of stress during the working condition can also affect the corrosion properties of the composites. Crevices about the interface of matrix-reinforcement could cause pits and the inherent difference in their electrochemical behavior causes galvanic corrosion, therefore some composites also exhibit multiple corrosion mechanisms. But corrosion control can be achieved by optimum material selection and processing conditions to adapt to the working environment. Tailoring the microstructure along with understanding the reaction between its constituents helps to improve the corrosion resistance of the composite and enhance its overall performance.

Glossary

Anti-icing Anti-icing surfaces are profoundly hydrophobic and are extremely difficult to wet.

Anti-oxidation It is used to protect metallic components from the oxidation attack.

Anti-soiling It is used to reduce soiling or yielding them easier to wash.

Coating It is used to provide protection and/or functional properties to the substrate's surfaces.

Composite It is a physically distinct and chemically inhomogeneous mixture of two more different phases or solids.

Corrosion It is a kind of chemical attack occurred at the surface or subsurface of solid materials.

Fog-resistance It is a resistance of the material against a small droplet of condensed water on substrate from the surrounding atmosphere.

Hydrophobicity It is a property of material's surface which repels the water molecules.

Metal matrix composite It is a physically distinct and chemically inhomogeneous mixture between two more different phases in metallic (i.e., metal or alloy) matrix.

Oleophobicity It is a property of material's surface which repels lipid or oleic molecules.

Scratch resistance It is a property of material's surface that resists the producing continuous mark, visible to the naked eye, with minimum loading.

Self-cleaning It very similar to the anti-soiling coating.

Self-healing It is a type of coatings that can autonomically repair and prevent surface attacks.

Superelectrophobicity It describes the nature of foreign atoms in a metal, i.e., known as "solvent of electrons" and it presents between the impurities having closed electron shell structure, which leads their dissolution properties in a metal.

Superhydrophobicity It is a property of material's surface composed of such water-repellent materials on that water droplets bounce such a manner that it actually seem backlash bounce off like as rubber balls.

Introduction

Recently, the coating on metal matrix composites (MMCs) is emerged as a fascinating material to the researchers in the world due to their various mechanical, thermal, electrical, biocompatible properties in several advanced applications (Pramanik *et al.*, 2017). MMCs are a kind of composite materials in which one metal or alloy must be as a form of matrix phase, which can be reinforced with at least one other reinforcing material of either any high melting point metallic material or any ceramic material. In another word, the metal matrix is a continuous kind of monolithic material into which the reinforcement is dispersed. Mainly in structural applications at low or ambient temperature, the most commonly used matrix material is a low-density metal or alloys such as magnesium (Mg), aluminum (Al), titanium (Ti), nickel (Ni), copper (Cu), or their alloys, which provides flexible support to the reinforcing agent. But in high-temperature applications, the metallic matrices based on cobalt (Co), Co-Ni alloy, and so on are commonly used. On the other hand, reinforcing particulate (i.e., particles, discontinuous fibers, whiskers, short fibers, chopped fibers, etc.) do not always deliver a purely structural function, instead provides improved physical characteristics such as tribological properties including, friction coefficient, wear resistance, thermal conductivity, thermal expansion coefficient and so on (Pramanik *et al.*, 2017). It has been found that the randomly dispersed discontinuous MMCs are isotropic in nature (Böhm *et al.*, 2002) and thus, they are easy to be worked with different conventional metalworking processes such as forging, rolling extrusion, machining, and so on (Barnes *et al.*, 1996). Further, using continuous aligned reinforcement with monofilament wires, fibers, laminate or fabrics material such as alumina (Al_2O_3) (Zhai *et al.*, 1997), silicon carbide (SiC) (Zimmerman *et al.*, 2002), and carbon fiber (CF) (Shirvanimoghaddam *et al.*, 2017), a certain directional or anisotropic structure can be developed to influence the strength of MMCs. In particular, as the specific strength, σ_{sp} (i.e., $\sigma_{sp} = \sigma_{UST}/\rho$ where σ_{UST} is ultimate tensile strength (UTS) and ρ is density) and specific modulus, E_{sp} (i.e., $E_{sp} = E/\rho$ where E is Young's modulus) are very crucial for comparing the composite's overall mechanical properties, a typical comparison of potential matrix and reinforcement materials aerospace applications is depicted in Fig. 1 (Rohatgi and Schultz, 2007; Allison and Cole, 1993).

There are significant applications of MMCs in various fields, particularly in automobile sectors (Prasad and Asthana, 2004; Rohatgi, 1991; Miracle, 2005), aeronautical (Deuis *et al.*, 1998), biomedical engineering (Witte *et al.*, 2007), sports industries, and so on (Clyne and Withers, 1995). The need for high-performance materials to acquire challenging demands is being increased tremendously in those fields. The main advantage of the MMCs in comparison with their monolithic alloys is tunable specific desired properties (Ataollahi Oshkour *et al.*, 2014). The most important desired properties of the MMCs are listed as (Moghadam *et al.*, 2014).

Fig. 1 A typical specific modulus vs. specific strength relation of the different composite, matrix, and reinforcement materials used for aerospace applications.

- Density or bulk density
- Specific strength
- Specific modulus
- Specific stiffness

- Thermal conductivity
- Coefficient of thermal expansion
- Hydrophilicity

These characteristics of the composites can easily be tuned by varying the type of matrix, type of reinforcing agents, reinforcement size, shape, content, and distribution. Further, the innovative use of several engineered reinforcements such as nano-sized particles, shape memory alloy (SMA) fibers, hollow balloons, and so on is being considered to develop some next-generation MMCs. However, almost all metallic substances are corrosive in nature (Bobić *et al.*, 2010). Also, MMCs are mostly manufactured at elevated temperatures which helps in the formation of diffusion bond between the reinforcement and matrix interfaces (Lee and Chen, 2005; Cotterill and Bowen, 1993). When the temperature cools down to ambient condition, residual stress generated in the MMCs owing to the mismatched coefficient of thermal expansion (CTE) of each component. This residual stress in the MMCs due to the manufacturing process significantly affects their mechanical properties in any loading mode. Particularly, the residual stress also provokes stress corrosion in MMCs.

Some advanced MMCs, which have recently been developed for use in various automotive components are illustrated in Table 1 (Moghadam *et al.*, 2014).

Sometimes, the reinforced particulate surface needs coating to prevent a chemical reaction by reaction with the matrix material. For instance, carbon fibers (CFs) are widely used in Al or Al alloy matrix composites. But, carbon of CF may react with Al to form a water-soluble aluminum carbide (Al_4C_3) compound on the surface of CF causing a reduction in ductility (Chang *et al.*, 2005). Hence, the carbon fibers are normally protected with Ni (Kar and Sathiyamoorthy, 2009; Kushwaha *et al.*, 2011; Kar *et al.*, 2009), Cu, titanium boride, platinum (Sharma and Kar, 2015a,b), tin (Bhattacharya *et al.*, 2019), lithium (Yadav *et al.*, 2019), hydroxyapatite (Pramanik and Kar, 2011), carbon nanotube (Sharma and Kar, 2014; Singh *et al.*, 2018), etc., coatings to improve the performance of material (Chang *et al.*, 2005; Singh and Balasubramanian, 2009).

Similarly, other fibers used in composites are glass fibers (Rahaman and Kar, 2014, 2011; Rahaman *et al.*, 2010), tungsten fiber (Agarwal *et al.*, 2010), kenthal fiber (Yamini Sarada *et al.*, 2009; Rahaman *et al.*, 2008), etc.

Protective Coatings

The protective coating is applied to the surface of an object, also called substrate to cover it for making functional, decorative, or both. The conventional coatings are generally applied to protect the substrate from corrosion, oxidation, chemical attacks, wear,

Table 1 Advanced MMCs developed for utilization in automotive and other applications

Property	Material	Application
Corrosion	Co-electrodeposited and embedded nanoplatelets of Na-montmorillonite (up to 0.15%) as reinforcement in Cu ₉ -Ni alloys MMCs	Micro-electromechanical system (MEMS) devices (Thurber <i>et al.</i> , 2018)
Wear resistance: High	Silicon carbide (SiC), alumina (Al ₂ O ₃), and/or graphite-reinforced micro and nano MMCs	Bearing surfaces, cylinder liners, pistons, cam shafts, tappets, lifters, rockers, brake components (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)
Wear resistance: Excellent (at 200°C)	Rapidly solidified nanocrystalline Al alloys and Al/SiC nanocomposites (Matrix: Al-Ni-Y-Co, Al-Si-Ni-Ce, and Al-Fe-Ti-M, where M: Cr, Mo, V, Zr)	Automotive industry (Rohatgi and Schultz, 2007; Takagi <i>et al.</i> , 2001)
Wear resistance: Good	Electro-co-deposited Ni-Al ₂ O ₃ nano-particle reinforced MMC coatings	MEMS devices (Rohatgi and Schultz, 2007; Thurber <i>et al.</i> , 2018)
Hardness (2.3 GPa)	Cu-Al ₂ O ₃ (1 wt/wt) nanocomposites (produced by high-pressure torsion technique)	Automotive industry (Rohatgi and Schultz, 2007; Islamgaliev <i>et al.</i> , 2001)
High thermal stability	Al/SiC (20–40 wt% SiC of size 9–38 μm)	Heat sinks for electronics and housings & mirrors for optics, high speed equipment for manufacturing, brake rotors for vehicles (Kuang and Sturdivant, 2017; O'Fallon Casting Pvt. Ltd, 2019)
	Al/SiC (Casting product)-SA301/SA401	Semiconductor processing equipment, Aerospace: heat sink, variable speed refrigerators, inverter, variable frequency drives (VFDs), uninterruptible power system, hybrid vehicles, electric vehicles, and high speed rail train (RichEnergy Technology Co., Ltd, 2010)
High creep strength	Cu-Al ₂ O ₃ (1 wt/wt) nanocomposites (produced by high-pressure torsion technique)	Automotive industry (Islamgaliev <i>et al.</i> , 2001)
Light weight, energy absorption	Fly ash cenosphere- and low-density ceramic microballoon-reinforced syntactic foam MMCs	Crumple zones, pedestrian impact zones, batteries, frame members and reinforcements (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)
Self-cleaning	MMCs with hydrophobic reinforcements, biomimetic coatings, and surface finishes	Water jackets, water pumps, exposed metallic components (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)
Self-lubricating	Micro and nano MMCs incorporating graphite, MoS ₂ , TiB ₂ , hexagonal boron nitride (h-BN), or other solid lubricants	Bearing journals, constant velocity joints, pistons, cylinder liners, gear surfaces (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)
High thermal conductivity	Micro and nano MMCs reinforced with high-conductivity carbon, diamond, or cubic boron nitride (cBN) powder	Cylinder liners, brake components, water passages, catalytic converters, turbo/supercharger components, electronics packaging (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)
Electrical conductivity	Montmorillonite nanoplatelets (up to 0.15%) reinforced Cu ₉ -Ni alloys matrix MMCs	MEMS devices (Thurber <i>et al.</i> , 2018)
Strength High	Micro and nano MMCs reinforced with SiC or Al ₂ O ₃ particles, carbon or Nextel fibers, CNTs, and in situ ceramics	Connecting rods, brake calipers, brake rotors, brake calipers (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)
Tensile strength (680 MPa)	Cu-Al ₂ O ₃ (1 wt/wt) nanocomposites (produced by high-pressure torsion technique)	Automotive industry (Islamgaliev <i>et al.</i> , 2001)
Strength Good	Montmorillonite nanoplatelets (up to 0.15%) reinforced Cu ₉ -Ni alloys matrix MMCs	MEMS devices (Thurber <i>et al.</i> , 2018)
Low cost	MMCs containing fly ash or waste sand as fillers	Intake manifolds, accessory brackets, low-load brackets, oil pans, valve covers, alternator covers, water pumps (Moghadam <i>et al.</i> , 2014; Macke <i>et al.</i> , 2012; Kuang and Sturdivant, 2017)

etc., and also, might be for decoration, texturing, or printing words and images. In general, anticorrosion coatings are used to protect metallic surfaces from corrosive environments by applying paint. It has huge applications such as, automotive industries, new construction components, maintenance, and repair, which includes major refurbishments and onboard maintenance (OBM). The major components of paints are a binder (e.g., epoxy, chlorinated rubber, alkyd, etc.), pigment or extender (e.g., zinc, zinc phosphate, Al, etc.) and solvent (e.g., latex, epoxy, etc.). Oxidation protective coatings are generally applied for temperature applications, particularly on structural materials in aeronautics and aerospace industries. This coating is mainly used to block the contact between oxygen and the substrate materials to achieve the anti-oxidation effect at high temperatures. In this method, generally, ThO₂, Y₂O₃, HfO₂, Al₂O₃, SiO₂, and so on like oxide ceramics are used as coating materials, which have lower oxygen diffusion to inhibit the diffusion of oxygen to the substrate effectively. Chemical protection coatings are mostly used in the chemical and nuclear industries to make the components inert in contact with different harsh chemicals such as concentrated sulfuric acid (H₂SO₄), sodium hypochlorite (NaOCl), hydrochloric acid (HCl), sodium hydroxide (NaOH), and so on. Generally, silicone, polyurethane, novolac, epoxy, and so on are used as chemical resistive coating materials. Wear resistance coating is generally used in metallurgical and many manufacturing industries. The main features of wear resistance coating are high hardness, high fracture toughness, high bond, low porosity, and uniform quality. Normally, tungsten carbide, tungsten carbide cobalt

chrome, titanium carbide, silicon carbide, boron nitride, and so on are used as a wear-resistant coating material, which can be made by different thermal spray techniques. Other advanced protective layer coatings are discussed in the following sections.

Classification of Protective Coating

The life span of metallic objects such as vehicles, the exterior and interior surfaces of buildings, etc., is intended to prolong by the coatings (Ho *et al.*, 2018). The prolonged life span of the protected objects would significantly decrease the required frequency for repair or replacement, in turn, followed by the cut down of long-term environmental impairment and the overall ecological- or carbon-footprint. Protective coating technology on MMCs or any other materials can generally be classified into three types such as (1) painting, (2) coating, and (3) surface treatment as depicted in Fig. 2.

Painting

Painting is done on the materials using only paints by various techniques. Paint generally contains acrylic and/or vinyl resins in liquid form. It flows as a layer followed by the formation of a continuous, flexible, and waterproof film of plastic after the evaporation of solvents, which can be either water or volatile organic compounds (VOCs). The types of painting, the process concepts, and applications are illustrated in Table 2.

Polymeric and pigment-based painting materials hold an enormous global market (Ho *et al.*, 2018). They are available as a solvent or water-based formulations and the main difference between them is the bulk solvent carriers which are the VOCs and water, respectively. However, both are used to protect the metallic surfaces, such as metallic infrastructure, exterior part of the vehicles, interior surfaces of buildings, and so on (Marrion, 2004). The pigment coatings (latexes) or solvent-based paints emit

Fig. 2 Advanced protective coatings and their functional properties.

Table 2 Painting methods, concepts, and applications of the process

Painting methods	Concepts of the process	Applications
- Spray, - Electrostatic, - Electrodeposition, and - Powder.	- Organic solvents are evaporated upon drying to form a - continuous, - flexible, and - waterproof film of plastic.	- General uses: - Surface decorations, - Anti-rusting and - Anti-corrosion. - Used as functional painting: - Electro-conductive painting - Non-adhesive painting, and - Lubricating painting.

higher VOC emissions than water-based paints (Matheson, 2002). The mechanisms, advantages, and disadvantages of the solvent-based and water-based coatings are presented in the following section.

- **Solvent-based painting**

In solvent-based and pigmented (paints) based paintings, polymer binder content around 25%–35% (v/v) in a homogeneous solution with an organic solvent of around 50%–75% (v/v) are there in addition to opacity agents or pigments, and many other additives, including bacteriocides or rheology modifiers (Ho *et al.*, 2018; Keddie and Routh, 2010). Polymers, which are generally used for these coatings, should be substantially hydrophobic in nature to render water resistance properties. Further, the painting polymers should have appropriate hardness for providing good mechanical as well as abrasive strengths. The hardness of the painting polymers generally depends on their glass transition temperature (T_g).

- **Mechanism**

In the case of solvent-based paintings, the film formation process starts immediately after the application of paint through the evaporation of organic solvents from the film's surface. It leads the polymer chains to reach close to each other and forms an entangled network structure on the MMCs substrate surfaces (Keddie, 1997). Here, crosslinking agents are usually employed in the formulation of paints to form covalently bonded chains to each other after drying which further improves the mechanical properties as well as the solvent resistance of the coating film. The solvent-based paintings are good as high-quality and durable coatings. They exhibit a smooth film surface on MMCs due to the slow evaporation of the solvent (Ho *et al.*, 2018).

- **Disadvantages**

However, the main disadvantage of the solvent-based coatings is the usage of a huge amount of organic solvents, which can cause environmentally as well as health problems. Further, the solvent poses other risks such as flammability, smog formation, and inhalation (Matheson, 2002; Kim, 2011). Therefore, in new studies, the solvents are released into the atmosphere using some sophisticated coating techniques. However, in most of the applications, the solvents are released directly into the atmosphere or environment and can be absorbed via the skin or lungs (Ho *et al.*, 2018; Kim, 2011; Gaines *et al.*, 2011). On the other hand, water-based is safer for the environment as well as human's or animal's health (Ho *et al.*, 2018).

- **Water-based paint**

Water-based paints contain an aqueous suspension of about 50–300 nm polymer particles and several additives including opacity agents, pigments, coalescing supporters, etc (Keddie and Routh, 2010).

- **Mechanism**

Film formation after the application of paint occurs by water evaporation upon drying. It brings the particles closer in contact. It follows a complex film formation process. In this process, the individual polymer chains diffuse across the interparticle boundaries. It leads to obtain a gradual coalescence of the particles into a coherent film (Ho *et al.*, 2018; Keddie, 1997). The softer polymer particles having a low- T_g are generally used to form an efficient film. Alternatively, high- T_g polymer particles can also be employed however, this approach needs homogeneous heating of the MMCs substrate at an appropriate temperature, which is rarely used (Ho *et al.*, 2018; Paul, 1977).

- **Disadvantages**

Water-based paints work poorly when they are used at low temperatures, particularly, below 10°C due to insufficient inter-particle diffusion of polymer chains and the slow evaporation of water. As a result, the film lacks quality and durability, i.e., poor resistance to mechanical abrasion (e.g., cleaning or scrubbing) and “chalking” defects due to the incomplete coalescence of latex particles (Mason, 1973; Malshe and Waghoo, 2004). Chalking defects are not generally found in solvent-based paints since the polymers are fully dissolved in the organic solvent instead of being suspended. Also, as the film surface holds microscale roughness from the coalesced individual particles, high glossy coatings are normally difficult using water-based paints (Ho *et al.*, 2018; Wang *et al.*, 1992; Carter *et al.*, 2014). Normally for water-based paints, a small amount of VOC is added (e.g., 50 g VOC/L) as the coalescing relief.

Coating or functional coating

Although the coating is a generic term that refers to the substance applied on the outer layer of a substrate, a thin layer of any inorganic functional material on the substrate is termed as a functional coating. The main difference between coating and painting materials is that while the coating is a thin outer layer of an inorganic substance, painting refers to the layer of organic substance on the substrate. For example, inorganics are present as metallic layers or ceramic powders in the coating, while organic materials are present as volatile polymers or plastics in painting.

In functional coatings, the addition of nanocrystalline and nanofiller phases enhances the functional performance (Thurber *et al.*, 2018; Ma *et al.*, 2017; Digital Library, 2019). Types of coating, concepts of the process, and applications are illustrated in Table 3.

The coatings on MMCs can be done by several techniques including, stir casting, hot pressing, physical vapor deposition (PVD), chemical vapor deposition (CVD), diffusion bonding, powder metallurgy, and so on (Thurber *et al.*, 2018; Rosso, 2006). However, some drawbacks are also there for these methods. For example, at high temperatures or under a vacuum in the production, several difficulties have to be faced to control the film thickness and also to maintain the cost (Digital Library, 2019). However, the interest is increasing continuously due to the more availability of cheap nanoparticles.

Table 3 Types of functional coating, concepts, and applications of the process

Functional coating type	Concepts of the process	Applications
Electroplating	Electroplating is a metal coatings (metal plating films) formation process on metallic substrate's surfaces, which are submerged in ionic solutions. The main principle of this method is electrochemical reduction effect.	Applications ranges from micro components to bulk products in: - equipment, - automobiles, - anti-corrosive plating for home appliances - plating for ornaments, and - functional plating.
Electroless plating	- It is a metal or alloy depositing process through electrochemical reactions. - It does not use electricity. - The electroless plating solution contain a reduction agent which substitutes the electricity. - Plating can be done for any kind of material: - metals - plastic - fabrics, and - paper. - It produces more uniform film thickness - However, it is slower than electroplating process. - This process is quite different from chemical plating by substitution reaction.	Mostly, this coating method is used in integrated circuit manufacturing for plating of different metals such as: - cobalt, - nickel, - palladium, or - copper onto one of two types of substrate surfaces (Kellam, 1999)
Vacuum Plating Techniques: - Vacuum Vapor Deposition (VVD), - Sputtering, - Ion Plating, - Ion Nitriding, - Ion Implantation.	Gases or ions of metals, oxides, and nitrides are deposited by vapor deposition in vacuum chambers.	Titanium nitride is used to make gold color coating on MMCs. It is further used for watch casing, decoration and jewelry purposes.
Chemical Coating	- In this process, thin films of sulfide, oxide, and carbides are coated by chemical reactions such as: - Chrome treatment: in post zinc plating, - Parkerizing: phosphate film coating, - Black oxide treatments: on steels, and - Chromic acid coating: on aluminum based materials.	To enhance paint adhesion, chemical coating is used for coloring the metals or alloys to enhance corrosion resistance, and to get priming of surfaces, which are to be painted.
Hot Dipping It is also known as Tempura plating or Dobuzuke plating.	- Products or substrates are dipped in dissolved metals such as: - tin, - lead, - zinc, - aluminum, and - solder - It forms the metallic film on the product's or substrate's surface.	It is most commonly used in zinc plating on steel towers.
Thermal Spraying	- Metals and ceramics (e.g., metal oxides, carbides, or nitrides) powders are sprayed onto surfaces using - flames, - arcs, - plasma streams.	- Typically it is used as below: - spraying for wear prevention - for paint primer based coatings on larger structural objects
Metallic Cementation Double Layer Ion Metallic Cementation	- In metallic cementation, surface alloy layers are formed by covering the surfaces of heated metals via metal diffusion. - Here, both the pre-plated products and the products in powdered metal form to be coated are heated. - Double layer glowing discharge phenomenon is used in double layer ion metallic cementation - Coating depths up to 100 μm can be reached.	Metallic cementation of steel specimens (Zhong <i>et al.</i>, 1982) is done for: - ion-tungstenizing, - ion-molybdenumizing and - ion-chromnickelizing, etc.

Table 4 Types of surface coating treatments, concepts, and applications of the process.

Surface coating treatment method type	Concepts of the process	Applications
Surface Hardening: - Carburizing, - Nitriding, - Induction Hardening - Lase hardening	In this process, the metal surface is altered by surface hardening methods which improve the wear resistance and fatigue endurance.	Surface hardening by carburizing, nitriding, induction hardening, and laser hardening is very common for steel products.
Anodic Oxidation	- In the anodic oxidation method, electrolysis is occurred at the anode in a suitable electrolytic solution to generate thin film on the product's surface. - Here, thin films are generally made of various light metals, such as: - nickel - aluminum, - magnesium, - titanium, and - some oxides. - These coatings (anodizing films) may be porous in nature. - In this treatment, the hard coating can also be developed at a low temperature.	It is used generally for color or dye coating of materials for construction applications, e.g., - vessels - sashes, and so on.

Surface treatment

The surface treatment is a kind of surface modification techniques to achieve required corrosion or oxidation resistance or to create new features on the surface without damaging the desired basic or mechanical properties of the substrate. Here, the surface texturing or restructuring is done by some surface modification techniques using external coating materials. However, in some special cases such as, for specific functional applications, the external substance or functional groups might be used to achieve the targeted performance. Types of surface treatment, concepts of the process, and applications are illustrated in [Table 4](#).

The incorporation of functional groups may include some specific techniques such as oxidation (e.g., ozonization or peroxidation), halogenation (e.g., chlorination or fluorination), nitration, amination, and so on. In general, the functionalization of monomers or polymers onto the substrates' surfaces is done to get a more stable surface structure. The most common techniques used for the incorporation of functional groups to the polymer treated surface are flame treatment, corona treatment, plasma, and radiation, which can increase the surface energy of a biopolymer. However, these techniques may have some disadvantages such as wettability, shelf-life, storage-instability, and so on. For example, the poor stability of the functionalized surface is a terrible problem, particularly in functional biopolymers for in vivo biomedical applications. It may cause unexpected features by alteration of the substrate's properties and/or the degradation profile. As a result, the possibility of undesired side effects may appear.

It has plenty of advanced applications. For example, surface modification techniques can significantly improve the long-term in vivo performance of biomedical implants and provide them with certain biological functions ([Hasan et al., 2013](#); [Moradi et al., 2016](#); [Manna et al., 2016](#); [Pramanik and Kar, 2012](#); [Kar and Pramanik, 2014](#)). Minimum criteria for biomedical surface treatments are:

- Sufficiently high mechanical stability against shearing forces,
- Suitable for cleaning and sterilization,
- Locus and functionally oriented biocompatibility,
- Long-term chemical stability and degradation resistance.

Advanced Protective Coatings and Emerging Coating Technologies

Recently, researchers are extensively trying to explore advanced MMCs such as hollow particle-filled syntactic foams, metal matrix nanocomposites (MMNCs), and functional composites including self-cleaning, self-healing, self-lubricating, etc. There are several surface modification techniques, which are used to improve the resistive performance of materials. Recently, advanced protective coatings have been used to protect the surface and life of components by modifying their surface.

The protection of metallic materials including MMCs is an essential task in any application. The coating on MMCs is necessary not only for preventing them from corrosion ([Thurber et al., 2018](#)), but also for tuning their surface properties such as, hydrophobicity ([Nosonovsky et al., 2011](#)), superhydrophobicity ([Nosonovsky et al., 2011](#); [Tam et al., 2016](#)), superelectrophobicity ([Zhou et al., 2016](#)), oleophobicity ([Nosonovsky and Bhushan, 2012](#)), anti-soiling ([Nair and Dave, 2014](#)), self-healing ([Moghadam et al., 2014](#); [Rohatgi, 2014](#)), self-cleaning ([Moghadam et al., 2014](#)), fog resistance ([Pardo et al., 2006a](#)), scratch resistance ([Yih and Chung, 1997](#)), anti-icing ([Koivuluoto et al., 2017](#)), anti-oxidation ([Xu et al., 2014](#)), and so on, as depicted in [Fig. 2](#) for their various advanced functions.

Fig. 3 Comparisons of water contact angle for different surface types: (a) superhydrophilic, (b) hydrophilic, (c) hydrophobic, (d) superhydrophobic properties.

To achieve various functional properties of the metallic or MMC's surface, various coating technologies have been emerged in very recent; some of these are discussed below in the present article.

Hydrophobic Coating

Hydrophobic interaction is very important for understanding several natural phenomena. Since water is the most common solvent, the dissolution property of solutes in water is very interesting to the researchers. The hydrophobic interaction between molecules of hydrophobic solutes, e.g., fat, paraffin, wax, etc., producing from their repulsion of water molecules is liable for their isolation in water (Zhou *et al.*, 2016). Recently, superhydrophobic engineering materials are being designed based on their hydrophobic interaction for a variety of applications. Hydrophobic coating treatments are performed on metals to avoid the absorption of water molecules at the surface. The hydrophobic surface generally has low surface energy. Wetting or hydrophilicity depends on the stability of three-phase interfaces of solid, liquid, and gas. The surface wettability also depends on the roughness of the surface (Wenzel, 1936). A Cassie-Baxter state is a kind state found at the solid-liquid-air interfaces. It occurs in the presence of vapor at the interface of a water droplet and particle's surface owing to surface roughness (Cassie and Baxter, 1944). The contact angles of a water droplet on a hydrophobic surface should be more than 90° as depicted in Fig. 3. The water contact angle is widely calculated by using Young's equation given in Eq. (1) (Young, 1805; Isbilir *et al.*, 2018; Lin *et al.*, 2018).

$$\gamma_{VS} = \gamma_{SL} + \gamma_{LV} \cos \theta \quad (1)$$

where θ is the contact angle, γ_{SL} is the solid-liquid interface surface tension, γ_{LV} is liquid-vapor interface surface tension, and γ_{VS} is the vapor-solid interface surface tension (Rocha *et al.*, 2009). There have been so many hydrophobic coating techniques developed in recent years and some of them are listed below:

- Lithography technique
- Phase separation technique
- Templating processing technique
- Etching technique
- Sol-gel technique
- Electrostatic spinning technique
- Electrodeposition
- Electro-co-deposition
- Other methods of preparation

The functional molecules can also form bonds to a surface in a self-assembled monolayer (SAM) by changing their properties of surfaces. In hydrophobic coatings, the self-assembled monolayers (SAMs) are prepared by adsorption. The SAMs are such type of molecular assemblies that form spontaneously on the surfaces and organize as ordered domains. A hydrophobic functional coating with SAMs is depicted in Fig. 4. The main features of SAMs-coating as depicted in Fig. 4 are listed below.

- (1) The coating is ultra-thin (≤ 10 nm);
- (2) The self-arrange molecules on the substrate's surface are perfectly homogeneous and capable of complete surface coverage;
- (3) A monolayer has an affinity to the substrate's surface but not for within itself, implying there is no layer stacking or oversizing; and
- (4) Since the monolayer builds a covalent bond with the substrate's surface, it produces high abrasion resistance.

The SAMs-coating thickness may achieve up to the nanometer scale. These coatings can be done on almost all types of materials, such as metals, alloys, ceramics, glass, and polymers. The coating may help to resist abrasion, chemical effect, pH effect, and also physical abrasion. Therefore, in this coating treatment, the coatings can easily make the bond with various products of different classic industrial materials including, complex metal alloys or MMCs.

Superhydrophobic Coating

Superhydrophobic coating surfaces are extremely difficult to wet. Since the natural lotus leaves provide superhydrophobicity, it is also known as the “lotus effect”. A superhydrophobic coating on the metallic surface is composed of such water-repellent materials on that water droplets bounce like the backlash of rubber balls. A superhydrophobic coating is a thin layer applied on the surface to strongly repel water molecules. A basic comparison among hydrophilic, hydrophobic, and superhydrophobic surfaces is schematically shown in Fig. 3. The typical water contact angle of a superhydrophobic surface is more than 150° . By little tilting the surface even up to 10° from the horizontal position, the droplet can cause simply bead up and roll off. The superhydrophobic (ultrahydrophobicity) coating materials can able to rebound the entire water droplets after hitting on their surface (Liu *et al.*, 2014; Richard *et al.*, 2002; Khojasteh *et al.*, 2016; George *et al.*, 2016; An *et al.*, 2017). In this context, Richard *et al.* (2002), and Liu *et al.* (2014), showed beautiful illustrations, where a macro-sized water droplet hitting a super-hydrophobic solid and then bouncing like elastomer balls even after tilting the surface at different Weber numbers (W_e) and are schematically depicted in Fig. 5 (Liu *et al.*, 2014; Richard *et al.*, 2002; Khojasteh *et al.*, 2016; An *et al.*, 2017). The Weber number is a characteristic dimensionless quantity and it is the ratio of deforming inertial forces to stabilizing cohesive forces for a liquid flowing through a fluid medium. The W_e can be expressed as Eq. (2).

$$W_e = \frac{\rho u^2 r}{\gamma} \quad (2)$$

where u is the impact velocity, ρ is the density, r is the unperturbed radius of the liquid drop and γ is the surface tension of fluid (water).

This kind of coatings is generally composed of composite materials where one component increases the roughness and the other component reduces surface energy. Superhydrophobic coating surfaces can be made of hydrophobic material having a particular surface roughness. The rough surfaces can be obtained using several techniques as listed below.

- Layer-by-layer and self-assembly,
- Sol-gel processing,
- Etching,
- Electro-spinning method,
- Electrochemical deposition,
- Chemical vapor deposition, and so on.

It can be applied to different metallic substrates. For example, a Cu surface can be patterned with a square lattice of tapered posts and decorated with nanostructures by many researchers (Tran *et al.*, 2013). The post height, cross-section, and width may vary from 500 to 800 μm , 10–100 μm , and 100–300 μm . The post surface can be constructed by chemical etching following of a wire cutting machining (Tran *et al.*, 2013) to generate nanoflower structures of average diameter 2–4 μm . After applying a thin film coating of polymers, including some functional chemicals such as trichloro(1H,1H,2H,2H-perfluorooctyl)silane, a superhydrophobic feature having an apparent contact angle of over 150° is obtained (Liu *et al.*, 2014). Two methods of preparing the superhydrophobic coating are schematically depicted in Figs. 6 and 7 (Mertaniemi *et al.*, 2012).

Fig. 5 Different impact view of water droplets with superhydrophobic surfaces: (a) the water drop (at $W_e \approx 18$) becomes highly elongated before detaching from the superhydrophobic surface and gives rise to droplets; (b) a droplet after impacting on the taper-surface at $W_e = 14.1$ with the unique superhydrophobic surface topology at the horizontal position; (c) a droplet after impacting on the taper-surface at $W_e = 31.2$ with the unique superhydrophobic surface topology at tilted position. Redrawn and reprinted with permission from (a) and (b) Khojasteh, D., Kazerooni, M., Salarian, S., Kamali, R., 2016. Droplet impact on superhydrophobic surfaces: A review of recent developments. *Journal of Industrial and Engineering Chemistry* 42, 1–14.

Fig. 6 A lotus-leaf like mimicking of hierarchical topography and the wetting behavior obtained by using spray dispersion followed by CVD. A dispersion of microparticles (e.g., nanofibrillated cellulose (NFC) in ethyl alcohol (C_2H_5OH)) is first sprayed onto a solid surface (e.g., MMCs). Subsequently, the surface is coated with a chemical (e.g., (Tridecafluoro-1,1,2,2-tetrahydrooctyl)trichlorosilane (FOTS)) by CVD, to obtain a superhydrophobic coating on the solid surface. Redrawn and reprinted with permission from Mertaniemi, H., Laukkanen, A., Teirfolk, J.-E., Ikkala, O., Ras, R.H., 2012. Functionalized porous microparticles of nanofibrillated cellulose for biomimetic hierarchically structured superhydrophobic surfaces. *RSC Advances* 2 (7), 2882–2886.

In this coating treatment, the coating materials can form bonds easily with different modern and classic industrial products of different substrate materials such as complex metal alloys, MMCs, new generation plastics, vitreous products, and highly sophisticated microelectronic silicon components. The superhydrophobic coating nanoscale treatments significantly can improve their functional characteristics. The superhydrophobic coatings are highly water repellent. Thus, this superhydrophobicity facilitates the treated surfaces easy to clean the deposits and residues retained by water, dirt, and moisture.

Fig. 7 A lotus-leaf like mimicking of hierarchical topography and wetting properties using spray dispersion. A solution of NFC microparticles dispersed in the toluene medium is first allowed to react with FOTS or fluorinating the microparticles. The dispersed microparticles are subsequently washed to remove extra fluorine and finally, they are sprayed onto the solid substrate to obtain a superhydrophobic coating surface. Redrawn and reprinted with permission from Mertaniemi, H., Laukkanen, A., Teirfolk, J.-E., Ikkala, O., Ras, R.H., 2012. Functionalized porous microparticles of nanofibrillated cellulose for biomimetic hierarchically structured superhydrophobic surfaces. *RSC Advances* 2 (7), 2882–2886.

Fig. 8 A new design of radiation-tolerant material based on a layered radiation protection shell governed by an electrophobic interaction; ODS: oxide dispersion strengthened and μ_{He} : chemical potential of helium. *Note:* The μ of the impurities and bubbles keep on decreasing from the first metal alloy layer to the third oxide coating layer (marked by a downward arrow on the left in the vertical axis) owing to their electrophobicity and the interaction between of inert-gas impurity atoms and bubbles. Redrawn and reprinted with permission from Zhou, H.-B., Wang, J.-L., Jiang, W., *et al.*, 2016. Electrophobic interaction induced impurity clustering in metals. *Acta Materialia* 119, 1–8.

Superelectrophobicity Coating

Electrophobic and superelectrophobic interaction concepts are analogous to hydrophobic and superhydrophobic interactions, respectively. It describes the nature of foreign atoms in a metal, i.e., known as “solvent of electrons”. The superelectrophobic interaction presents between the impurities having closed electron shell structure controls their dissolution properties in a metal. The electrophobic or superelectrophobic interaction of different materials such as, He, Be or Ar leads to produce a close-packed cluster having clustering energy (E_c), which is nothing but “electrophobic interaction” energy. It can be proved using first-principles calculations using a universal power-law scaling formula in Eq. (3) (Zhou *et al.*, 2016).

$$E_c \propto N^{2/3} - N \quad (3)$$

where N is the number of atoms dissolved in a free electron gas, as well as metallic (tungsten (W) or Al) lattice. The design of radiation-tolerant material in an electrophobic interaction-based layered radiation protection shell is depicted in Fig. 8 (Zhou *et al.*, 2016).

This futuristic technique significantly progresses the basic insight and ability to predict the behavior of solute impurities in metals. It would be very useful in the coming future to design or modify the metallic surface for metallurgical, energy, and nuclear applications.

Oleophobicity Coating

Oleophobic coatings on the metallic surfaces efficaciously decrease the surface energy and wettability. As a result, the markedly high contact angle is obtained over a range of fluids including, polar (e.g., water or organic solvents) as well as apolar (e.g., hydrocarbon or oil).

The surface energy renders an ability of metallic surfaces to interact with its surrounding environments. It can be computed by measuring the contact angles of at least three different known fluids. The contact angle (θ) is evaluated by measuring a cross-section of a droplet on a flat solid surface and depicted in Fig. 3. The solid surface is considered between the outline of the droplet and the point at which it meets the solid surface.

The oleophobic coatings are highly water, dirt, and moisture repellent. Thus, this coating renders treated surfaces extremely easy to clean specifically the oil, which cannot adhere or smudge to these surfaces. Also, these coatings show dual merits besides their oleophobic nature, so one-ways of a clean cloth or absorbent paper can be cleaned fully.

Anti-Soiling Coating

Anti-soiling coating is a new technology being used to reduce the soiling or making easier to wash. Anti-soiling coatings can be both types either hydrophilic or hydrophobic. The hydrophilic anti-soiling coating has a large surface energy and provides a cleaning action by flowing water (Isbilir *et al.*, 2018). This “self-cleaning” coating is being claimed to facilitate “active” cleaning. It is generally aided by a photoactive titania (TiO_2) layer. The TiO_2 layers can break down organic chains and make the surface easier to clean. However, one disadvantage of TiO_2 materials is that it increases the reflectivity of the cover glass (Kesmez *et al.*, 2009). Since hydrophobic surfaces show low surface energy, they yield fewer adhesion properties for soiling onto the surface. Thus, a hydrophobic anti-soiling coating also helps water droplets to roll off the surface more easily in addition to discharge the dust, dirt, and other forms of soiling (Isbilir *et al.*, 2018). A sol-gel anti-soiling coating process is depicted in Fig. 9.

It has tremendous application in photovoltaic (PV) solar modules where the soiling of solar module cover glass significantly reduces the power output of the module. Soiling creates an accumulation of dust and dirt on PV modules. The soiling causes a

Fig. 9 A schematic of the sol-gel anti-soiling coating process. Redrawn and reprinted with permission from Jesus de, M.A.M.L., Timò, G., Agustín-Sáenz, C., *et al.*, 2018. Anti-soiling coatings for solar cell cover glass: Climate and surface properties influence. *Solar Energy Materials and Solar Cells* 185, 517–523.

terrible loss in PV power plants. Soiling may also cause over 5% reduction in PV system energy output per year in locations without frequent rainfall. Therefore, anti-soiling coatings are applied to the cover glass surface of solar cells to reduce adhesion. It assists the surfaces easier to immaculate and is resilient as well as resistant to environmental damage. So, reducing the average annual energy loss in the PV power plants owing to soiling by even a small amount could have immense value in terms of expanded energy production, particularly for utility-scale projects.

The quality of the anti-soiling coating can be evaluated by the soiling ratio (SR). The SR of a module can be computed for each minute of a data set by dividing the measured maximum power of the module by its expected maximum power when it is cleaned, and soil-free. Thus, the SR can be calculated at each minute, for each photovoltaic module using Eq. (4) (Gostein *et al.*, 2016, 2015).

$$SR = \frac{P_{max}}{P_{max,0} \cdot (1 + \gamma \cdot (T - T_0)) \cdot (G/G_0)} \quad (4)$$

Where, P_{max} = measured maximum power of the module in its soiled state, $P_{max,0}$ = expected calibration value for the module's maximum power when clean and at a reference condition (e.g., standard test condition, STC), γ = temperature coefficient of maximum power, T = measured module temperature, T_0 = module temperature at the reference condition (e.g., 25°C at STC), G = measured plane-of-array irradiance determined from the clean reference cell, and G_0 = irradiance at the reference condition (e.g., 1000 W/m² at STC) (Gostein *et al.*, 2015).

Self-Healing Coating

Self-healing coating is a type of coatings that can autonomically repair and prevent surface attacks such as corrosion of the underlying substrate. It can be created through homogeneous dispersion of microencapsulated healing agents in a polymeric film. These healing agents are normally released into the damaged region to passivate the substrate during self-healing the damage. This self-healing coating approach is quite common. It is efficient for both models and industrial coating systems. A self-healing polymer coating material is depicted in Fig. 10(a) (Cho *et al.*, 2009; Zhang and Li, 2016). In this process, the self-healing coating consists of a microencapsulated catalyst (whitish blue) and phase-separated healing agent droplets (accent red) in a matrix (orange) on a metallic substrate (accent aqua). After the damage to the coating layer, it releases catalyst (yellow) and healing agents (gray). Then, the mixing of healing agents and catalysts occurs in the damaged part. Finally, the damage healed by cross-linked polymer, protecting the substrate from its surrounding environment (Cho *et al.*, 2009). In Fig. 10(b), schematic representation of a self-healing process of an MMC subjected to tensile loading is depicted (Moghadam *et al.*, 2014; Zhang and Li, 2016). When a self-healing MMC tensile bar (ash) containing aligned SMA wires (brick-red) fails in tension, the SMA wires form a bridge in the crack (II); but upon heating (red-coils ON), the SMA wires pull the edges of the crack together and the matrix partially melts (III); Due to cooling (gray-coils OFF), the bar results in solidification of the matrix and bonding of the crack surfaces (IV). Redrawn and reprinted with permission from Zhang, P., Li, G., 2016. Advances in healing-on-demand polymers and polymer composites. Progress in Polymer Science 57, 32–63.

hydrophobicity, can be analyzed by using optical tensiometers. The efficiency of a hydrophobic self-cleaning coating depends on the chemical composition and roughness of the surface and also on the adhesion of dirt particle to water droplet (George *et al.*, 2016; Sakka and Kozuka, 2005). The hydrophilic self-cleaning coatings are prepared based on the photocatalysis process. When the photocatalysts are exposed to light, they can break down the impurities. It is used in self-cleaning windows, which are commercially available. This kind of window generally cleans its surface in two ways. When the organic dirt is absorbed onto the window surface, it is broken down chemically by photocatalysis. Subsequently, the broken dirt particles are washed out by water by creating sheets owing to the low contact angles. TiO_2 is also a commonly used coating for hydrophilic self-cleaning surfaces owing to its favorable physical and chemical properties. Also, TiO_2 is non-toxic and chemically inert in dark conditions. It is also cheap, easy to handle, and widely well-known as in household chemicals (e.g., pigment in cosmetics and paint). The strong oxidation power and superhydrophilic characteristics of TiO_2 make it a potent material that is used as a self-cleaning coating especially in outdoor uses. The self-cleaning effect of a TiO_2 coated MMC substrate is illustrated in Fig. 11 (Nakajima *et al.*, 2000).

Fog-Resistance Coating

A small droplet of condense water on the substrate from the surrounding atmosphere may create several problems in many sophisticated instruments and applications. Due to the change in temperature and humidity, water condensates for droplets formation onto the substrates create several problems including, corrosion on metallic substances, obscured vision for glassy products, and so on causes several safety issues. Therefore, prevent fogging of interior helm visor during spacewalks was originally developed by national aeronautics and space administration (NASA).

The fogging problem is a very big issue in the world which causes a huge number of accidents and transport delays around the globe every year, particularly in the winter season. Fog-resistance coating component enhances permanent scratch-resistant properties and improves other surface characteristics. These anti-fog coating materials can be applied for thermoforming, including shaping and molding, without the annihilation of their original properties. Anti-fog coatings can prevent the buildup of mist on a variety of materials. Usually, fog appears due to the condensation of moisture on a solid surface (hydrophobic) and subsequently becomes tiny droplets, which can scatter lights. It is expected that a highly hydrophilic material absorbs condensed moisture. However, the highly hydrophilic materials become saturated very fast and thus, make it poor anti-fog coatings. Therefore, modification of such hydrophilic materials is essential. This modification is done with proper surfactants that include a domain of hydrophilic and hydrophobic segments and causes condensate to spread. It maintains the visibility of a coated substrate (La Casse and Creasy, 1999). The anti-fog mechanisms of hydrophilic coating material coated on MMCs substrate are depicted in Fig. 12.

Some important features of anti-fog products are:

- It is easy to apply even by spraying,
- No curing is needed,
- No permanent bonding or chemical bonding with the substrate is required,
- There is a saturation of coating with water,
- It is also cheap.

Fig. 12 Mechanisms of anti-fog coating on MMCs substrate: (I) substrate; (II) coating with an anti-fog film comprising water (H_2O) friendly polar functional groups such as ($-\text{OH}$, $-\text{NH}_2$, $-\text{COOH}$, $-\text{PO}$, etc) on the substrate and exposed in a fog environment; (III) bonding with hydroxyl (OH^-) group of water from the foggy environment via an optional polymer layer; (IV) a continuous (no disruption) thin film of water formed on the substrate's surface.

Pardo *et al.* (2006a), studied the corrosion properties of different fog-resistance coated silicon carbide particle (SiCp) reinforced Al matrix MMCs in salt fog environment. Kinetic mechanisms of corrosion for the Al-MMCs modified by cerium (Ce) based transition or electrolysis coating in a fog environment of a neutral salt was evaluated by gravimetric analyses as per ASTM B 117 standard method. Pardo *et al.* postulated that the kinetic constant or corrosion reaction rate constant can be reduced by the addition of SiCp, which reduces the surface area of the Al matrix. Whereas, the kinetic constant can be increased by the addition of Cu and Ni owing to the formation of an Al/Cu, Ni galvanic couple. But, Ce-based surface treatment reduced the kinetic constants by inhibition of cathodic reaction, which annihilated the growth rate of corrosion products (i.e., a layer of bayerite ($\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$)) and stabilizing the Al_2O_3 of original protective layer (Pardo *et al.*, 2006b). As a result, the corrosion resistance of the materials was increased. This effect was more prominent when the Ce-modified fog-resistance coated Al-MMC was carried out by electrolysis.

Scratch Resistance Coating

To improve the durability of the MMCs, the scratch-resistant property is very important. Since many metal matrices are very soft in nature, for example, Cu, Mg, Al, and so on, scratch resistance coating on their composite plays a crucial role particularly in the engineering applications where high wear resistance property is desired.

Scratch resistance coating on MMCs can be done by several methods as listed below:

- Electro-co-deposition (ECD),
- High-velocity oxygen fuel (HVOF),
- Thermal spraying,
- Hot isostatic pressing (HIP), etc.

Some aluminum 7075 based components, such as engine pistons experience severe wear while working under fairly high temperatures. Such components require adequate surface treatment to increase the scratch or wear resistance by lowering the friction coefficient (Devaney and Senthilvelan, 2014). The scratch-resistant coating can be done by the electro-co-deposition technique as depicted in Fig. 13 (Devaney and Senthilvelan, 2014).

ECD is a more beneficial technique in comparison to other coating methods, such as HVOF, HIP or thermal spraying, owing to its capability of continuous processing, faster deposition, homogeneous distribution, normal working pressure, low maintenance, ability to deal complex geometry, and reduced waste generation (Devaney and Senthilvelan, 2014). ECD is an effective technique to produce coatings on MMCs through the co-deposition of metallic and non-metallic particles along with pure metals or alloys. It can also significantly improve the corrosion resistance and tribological properties of the substrate. Recently, the co-deposition of ceramic particles such as SiC, WC, TiC, TiO_2 , Cr_2O_3 , Al_2O_3 , etc., along with metalizing (e.g., Ni plating, etc.) have been used to improve the wear resistance of plated parts (Szczygieł and Kołodziej, 2005; Hu and Chan, 2006; Aal *et al.*, 2007). The tribological characteristics of the coating using these methods mainly depend on the size, amount, and distribution of reinforced particles (Thiemig *et al.*, 2007). The surface morphology can be affected by the electroplating parameters, including current density, pH, temperature, bath composition, and stirring speed (Kilic *et al.*, 2013). It has also been found that the wear-resistance increases with increasing the SiC contents in the Ni/SiC composite coatings. Recent studies reveal that in the presence of SiC particles, the normal growth of Ni crystals gets hindered, thus develops more inter-crystalline bonding (Baghal *et al.*, 2012). But in the case of micron-sized particles, the co-deposition of homogeneous deposits is highly ambiguous due to the greater tendency in the agglomeration of the microparticles. The non-homogenous ECD may lead to reduce the wear-resistance of the coated substrate. In this context, since titanium diboride (TiB_2) is also famous due to its relevant properties such as, for its stiffness, hardness,

Fig. 13 A schematic electro-co-deposition (ECD) technique for scratch-resistant coating. Redrawn and reprinted with permission from Devaneyan, S.P., Senthilvelan, T., 2014. Electro co-deposition and characterization of SiC in nickel metal matrix composite coatings on aluminium 7075. *Procedia Engineering* 97, 1496–1505.

electrically, and thermally conductive, it can be used as a potent coating material on the soft MMCs. In a coated filler method, the surface of the hard particles (e.g., TiB_2 platelets) is first metalized by electroless plating process with matrix metal (like Cu) and subsequently electroplated with Cu to obtain metal-coated hard particles with desired concentration (Yih and Chung, 1997).

Anti-Icing Coating

Since anti-icing surfaces are profoundly hydrophobic, they are extremely difficult to wet. Applying a superhydrophobic coating on MMCs-surfaces converts them into a highly liquid and water repellent, easy to clean, and significantly boosts their anti-icing performance. Anti-ice coating reduces ice and wet-snow adhesion (sometimes: up to 80%) to the underlying substrates. It is used to prevent dangerous ice built up on the components. The advanced coating materials, for example, SuperAi (commercial name, NEI Corporation), can be applied directly to versatile substrate materials, including plastics, metals, MMCs, glass, concrete, and ceramics. It has very vital applications in engineering. A low-viscosity formulation material, which can spread quickly on the surface, is generally used as an anti-icing coating material and applied on the substrate's surface. It can even flow over surfaces of the complex structured components. Then, it quickly cures under ambient conditions.

According to some studies, the two key factors in obtaining superhydrophobicity for anti-ice properties are (1) lower surface free energy and (2) microscopic rough structures. It is to be informed that such a rough structure not only increases the surface superhydrophobicity significantly but also creates some anti-icing performances under certain conditions (Hasan *et al.*, 2013). The anti-icing property can be evaluated by the main two concepts: (1) icing-delay time and (2) ice-adhesion strength (Lin *et al.*, 2018). The ice-adhesion strength (τ) is calculated by using the Eq. (5):

$$\tau = F/A \quad (5)$$

where F is the critical force and A is the contact area of ice-column with the sample surface.

The adhesion of ice or wet-snow on the surfaces of various components of automobiles, aircraft, and so on results several serious aviation accidents and also gives a fatal threat to the safety of the crafts. In this context, an air crashing of flight (China Eastern Airlines MU5210 going from Baotou to Shanghai in November 2004) was suspected to be held by undesired ice-accumulation on the aircraft's surfaces. It caused a huge loss of lives as well as serious economic issues (Lin *et al.*, 2018). In frosting weather, the ice accretion caused a loss in control on operating speed and thereby the plane lost its lift. As a result, the ice reduced the critical angle of attack, particularly during the formation of the ice, at the leading edges of wings.

Anti-Oxidation Coating

Anti-oxidation is extremely useful for the utilization of MMCs in high-temperature applications. There have been numerous methods including, anti-oxidation coatings produced by various painting, coating, or surface treatments developed by several researchers particularly for protecting the metallic components from low-temperature oxidation, thermal oxidation, or high-temperature oxidation, corrosion, residual stress formation, and so. For example, Fu *et al.* (2017) had found several factors responsible for the oxidation of carbon steels based MMCs:

- The high silicon (Si)-coating can enhance the resistance to oxidation.
- The blisters formation can reduce oxidation.
- The solid-phase sintering reactions also can enhance anti-oxidation properties.
- Si and Cr played a key role in oxidation resistance.
- Anti-oxidation coating can significantly reduce the mass loss due to the oxidation of steel (nearly up to 85%).

Due to anti-oxidation coatings, several phases are developed on the surfaces of the substrate, responsible for reducing the further oxidation reaction to the substrate. Transition metal disulfides (MS_2 where M is molybdenum or tungsten) are used as anti-oxidation coatings on MMCs and also act as solid lubricants in various space motion mechanisms, which are very important for tribological applications (Xu *et al.*, 2014; Wang and Gao, 2014).

Particularly in high-temperature applications, the ceramic coatings are very widely used for reducing the oxidation of MMCs components. The main concept of applying ceramic coatings onto heat engine components is to provide improved oxidation protection. It also imparts corrosion protection for the substrate of MMCs and alloys. The anti-oxidation ceramic coatings also can be used to tailor the insulation, thermal conductivity, electrical conductivity, coefficient of thermal expansion (CTE), reflectivity, diffusivity, properties of MMCs, or alloys by using different ceramic coating produced by many conventional and advanced techniques (Pramanik *et al.*, 2017). The different methods are used to coat the surface of metals are (Thiruseelvam, 2015; Pavan and BR, 2018):

- Physical vapor decomposition (PVD) coating
- Chemical vapor decomposition (CVD) coating
- Ion coating
- Splash coating
- Electron beam evaporation (EBE) coating
- Flame spray (FS) coating
- Plasma spray (PS) coating
- Plasma sprayed ceramic (PSC) coating
- Sol-gel (SG) coating
- Detonation gun (DG) coating
- Reactive ion (RI) coating
- Hot isostatic press (HIP) coating
- Laser surface alloying (LSA) coating
- High-velocity oxy-fuel (HVOF)
- Thermal barrier (TB) coating

The thermal barrier coating is particularly very important for engine components. With a fuel additive, it drastically reduces exhaust emission (Sathiyagnanam *et al.*, 2010). Mild improvement in the thermal efficiency of the engine observes owing to the influence of thermal barrier coating (TBC). The smoke level can be higher in TB coated engine. The NO_x emission can be reduced up to 500 ppm for TB coated engine comparing with standard engines. Upon the addition of fuel-additives to the TBC engines, the NO_x emission can further be reduced to 100 ppm. The heat release rate can slightly be decreased owing to the influences of either TB coating lonely or TB coating along with fuel-additives (Sathiyagnanam *et al.*, 2010; Haşimoğlu *et al.*, 2008).

Some ceramic coatings on mild steel substrates are illustrated in Table 5.

Table 5 Some ceramic coatings on metallic substrates

Year	Coating substrate	Coating material	Method
1992	Different metals (Cu, Ni, Fe, Al)	ZrO_2 , SiO_2 , TiO_2 and $B_2O_3-SiO_2$	Sol-gel dip-coating method (Innocenzi <i>et al.</i> , 1992)
1997	Mild Steel	A mixture of α , δ , and γ phases of Alumina, and 100% $(Al-Cr)_2O_3$ alumina-chromia annealed up to 1300°C	Plasma spraying (Pavan and BR, 2018; Chraska <i>et al.</i> , 1997)
1998	Mild Steel ball indenter	ZrO_2 -8 mol% Y_2O_3 , i.e., yttria stabilized zirconia (8YSZ)	Plasma spraying (Pavan and BR, 2018; Wallace and Ilavsky, 1998)
2002	Steel surfaces	Zn and Zn-Al coatings	Electrolytic plasma processing (Meletis <i>et al.</i> , 2002)
2004	Mild Steel	$Ni-Al_2O_3$	Dip Coating (Pavan and BR, 2018; Marikkannu <i>et al.</i> , 2004)
2005	Metals (copper)	$Ni-Al_2O_3$ composite	Electrodeposition (Bahrololoom and Sani, 2005)
2008	Mild Steel	Alumina	Sol-gel method (Ruhi <i>et al.</i> , 2008)
2010	Mild Steel	Al/SiCp	Low cost oxy-acetylene thermal spraying (Torres <i>et al.</i> , 2010)
2010	Medium carbon steel disk and stainless steel rod	Nanostructured ZrO_2 -3 mol% Y_2O_3 , i.e., yttria stabilized zirconia (YSZ) coatings	Air plasma spraying (Liang <i>et al.</i> , 2010)
2013	Mild Steel	VC - Cr_7C_3 ceramic	Laser cladding surface treatment (Wu <i>et al.</i> , 2013)
2016	Ni based superalloy	Al_2O_3 anti-oxidation coatings	Cathode plasma electrolytic deposition (CPED) (Wang <i>et al.</i> , 2016)
2018	90:10 Cu-Ni alloy	Montmorillonite (Mt) nanoplatelets embedded into the metallic matrix from electrolytic baths comprising 0.05, 0.10, and 0.15% Mt	Coelectrodeposited (Thurber <i>et al.</i> , 2018; Digital Library, 2019)

Concluding Remarks

In this article, advanced protective coating technologies for different materials including, metals, alloys, and MMCs have been discussed. It has been found that almost all kind of solid materials such as metallic, ceramic, cermet, some polymeric, and their composite materials in the form thin film of powder, wire, rod, grain alteration or texture can be coated with proper technology to tune their most advanced functional properties such as hydrophobicity, superhydrophobicity, superoleophobicity, oleophobicity, anti-soiling, self-healing, self-cleaning, fog resistance, scratch resistance, anti-icing, anti-oxidation, and so many using suitable coating technology. Finally, it can be concluded that the superhydrophobic surfaces using emerged technologies such as superoleophobicity coating, anti-soiling coating, self-healing coating, self-cleaning coating, fog-resistance coating, and so on, would have tremendous functional sophisticated applications in future generations.

Introduction

The longevity of an implant biomaterial depends on the anchorage and integration between the implant and the living bone (Albrektsson *et al.*, 2003). There are various factors which determine the success of an implanted biomaterial, namely the form and structural characterization, stability, mechanical-loading, material property, location of the implanted site and host response (Legeros and Craig, 1993; Prasad *et al.*, 2019a). The key outcome is to finally derive a matrix which matches the bone in composition, structure and properties (Puleo and Nanci, 1999). Biocompatibility and mechanical strength are the most important pre-requisite characteristics of any implanted biomaterial to be employed for biomedical, orthopedic and dental applications (Gotman, 1997; Gasser *et al.*, 2000; Niinomi, 2008; Marti, 2000; Prasad *et al.*, 2019b). The host response induced by the implanted material and the degradation of the material within the body are the two major factors which determine the biocompatibility. Biocompatibility is fulfilled when there is no foreign body reaction within the tissue caused by the implanted biomaterial. The biomaterial should be non-toxic and should not elicit any allergic or negative inflammatory reactions to the host tissues (Morais *et al.*, 2010). However, the biocompatibility of a material is dependent on the physiological interaction between the host cells/tissues and the implants. If there is a derangement in the interaction between the host cells/tissues and the implanted biomaterial, the immediate reaction is thrombosis and fibrous encapsulation leading to the failure of the implanted material (Williams, 1987).

A biomaterial is said to possess adequate mechanical characteristics in order to elucidate the functionality of the implants mainly in the load bearing orthopedic applications. Metallic biomaterials are preferred to polymers because of their high mechanical strength and reasonable corrosion resistance. The metallic biomaterial should have good tensile strength, young's modulus, wear, corrosion resistance, bioactivity and biocompatibility (Prasad *et al.*, 2017). There are various biodegradable and non-degradable metallic biomaterials available as implant material for both load bearing and non-load bearing applications. Stainless steel (316L), cobalt chromium (Co-Cr) alloys, titanium (Ti)/titanium alloys and magnesium alloys have been used as implant materials (Geetha *et al.*, 2009; Paital and Dahotre, 2009) (Table 1).

In case of a trauma surgery, stainless steel (316L) has been proven to be a good metallic implant (Navarro *et al.*, 2008). It exhibits good mechanical strength, ductility, elastic property, easily manufacturability and is available at low cost. However, the drawbacks of stainless steel are low resistance to corrosion and less biocompatibility due to the presence of nickel content causing allergic reactions (Gotman, 1997), hereby limiting their usage for short-term temporary implant surgeries (Gasser *et al.*, 2000). Co-Cr metallic alloys have replaced stainless steel as a permanent implant material due to its excellent mechanical property and high corrosion resistance (Marti, 2000). Co-Cr combined with molybdenum (Mo) shows excellent corrosion resistance and high fatigue (Marti, 2000; Navarro *et al.*, 2008; Bensmann, 1999; Disegi and Eschbach, 2000; Ha, 2008; Heuberger, 2009; Marti *et al.*, 2000). Nevertheless, the main drawback of these materials is biocompatibility and allergic reactions (Breme *et al.*, 2002; Christensen *et al.*, 2000; Keegan *et al.*, 2008). Titanium and titanium alloys have excellent biocompatibility, mechanical strength, and good elasticity and cause no allergic reaction. Besides its excellent properties and its wide applicability, the drawbacks of these alloys are non-degradability and stress shielding effects. Apparently, there is a need for a second surgical procedure to remove the implanted titanium alloys (Daley *et al.*, 2004; Disegi, 1993; Shapira *et al.*, 2009; Thompson and Puleo, 1996; Thomsen *et al.*, 1997). The Young's modulus of titanium (110–120 GPa) does not match with that of the natural bone (10–20 GPa) thereby causing stress shielding at the implanted bone site (Heary *et al.*, 2017). Magnesium alloys are able to overcome the drawbacks of titanium alloys. Magnesium alloys are biodegradable, their Young's modulus (40–45 GPa) is a near match with the natural bone, thereby eliminating the stress shielding effect and avoiding the need for a second surgical procedure to remove the implanted material. Interestingly, magnesium alloys are biocompatible and are capable of undergoing complete degradation. On the other hand, zinc and iron alloys are also biodegradable and are successfully employed for various biomedical applications. This article will attempt to provide an in-depth discussion about the biocompatibility of various metal matrix composites used for biomedical applications in both load bearing and non-loading bearing scenarios (Tables 2 and 3).

Biomaterial and Cellular Interaction

Any material is said to be biocompatible when it does not disturb the normal body functions. Biocompatibility of any implant material depends on factors like size, shape, surface and composition of the material (Tang *et al.*, 2017). The implanted biomaterial should not cause any allergic reactions, thrombus formation, and should not alter the cellular elements in the blood and electrolytes. The implanted material should be within the body until the expected outcome of regeneration of the bone or tissue or an organ has

Table 1 Comparison between permanent metallic materials and biodegradable metals

Items	Permanent metallic materials	Biodegradable metals
Mechanical property	Stable over time	Degraded with time, and should match the tissue recovery process
Ion release	Unwanted, try to avoid	The released metal ions should be acceptable by the host locally and all over the body
Interaction with the surrounding tissue	Bio-inert	Bio-active
Application fields	Ubiquitous	Special applications

been attained. If the implanted material degrades faster than the regenerating tissue, the material will lose its mechanical and physical properties that would potentiate it to withstand the forces and the chemical changes acting on it. In reality, there is no one single material which remains intact throughout the implantation period without undergoing any characteristic changes. The pace at which the material degrades can be altered by the addition of an alloying element to it. The degradation products and ions released from the material will further trigger changes in the surrounding biological environment of the implant. Immediately after the implantation process, there is an initial inflammatory response elicited by the injured blood vessels. This mostly leads to blood clot formation, unlike in some cases it results in thrombosis (Velnar *et al.*, 2016). There is an event of changes in the plasma proteins and emigration of leukocytes to the implanted area. The most common cells found around the implant site immediately after the implantation are the monocytes and lymphocytes which are more pronounced in chronic inflammatory phase. If the chronic inflammation does not subside within 3 weeks of implantation, there is a high chance of persisting infection that can eventually lead to implant failure. Besides, the surgical procedure adopted during implant placement also plays a crucial role in the healing process. If injury to the tissues and vessels occurs during the implantation procedure, it leads to increased amount of granulation tissue formation surrounding the implant area after 3–5 days post-implantation (Pippi, 2017). The ultimate success or failure of an implant material depends on the initial interface between the implant and the surrounding bone. An indicator for poor biocompatibility is the formation of fibrous tissue between the implant and the surrounding bone (Prasadh *et al.*, 2020; Prasadh and Wong, 2018).

The degradation of implant material around the implant activates the phagocytes and the giant macrophages leading to the release of inflammatory cytokines causing inflammatory changes like fibrosis, osteolysis and porosis in the bone (Bitar and Parvizi, 2015). This further leads to the formation of synovial-like interface between the bone and the implant leading to the formation of granulation tissues leading to implant loosening. The degradation rate of the implanted material further affects the inflammatory reactions both near and away from the implant area. The increased degradation of the implant material further increases concentration of the metallic ions around the implanted area. These metallic ions cause changes in the biological cellular environment and alter the electric current affecting the cellular metabolism (Guillory *et al.*, 2019, 2016). The released ions from the degraded implants may cause localized to systemic effects within the body. There could be acute pain, swellings, tenderness and localized discoloration of the surrounding tissues. The increased ion concentration if not excreted completely would lead to toxic effects in the vital organs like kidney and liver causing metallosis (Guillory *et al.*, 2019; Bowen *et al.*, 2016). Metals like cobalt, chromium and nickel causes metallosis by causing destruction of hard and soft tissues surrounding the implant (Hong *et al.*, 2016; Jin *et al.*, 2018; Morin *et al.*, 2017). The metal ion by itself does not cause immune response. It is shown that the released metal ions from the materials combine with protein biomolecules surrounding the implant area, thereby inducing the inflammatory

Table 3 Metallic non-resorbable materials advantages, disadvantages and applications

<i>Materials</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Applications</i>
<i>316L Stainless steel</i>	Easily available and low cost Excellent fabrication properties Accepted biocompatibility and toughness	High modulus Poor corrosion resistance Poor wear resistance Allergic reaction in surrounding tissue Stress shielding effect	Bone Plates, Bone screws and pins, Wires etc.
<i>Co-Cr alloys</i>	Superior in terms of resistance to corrosion, fatigue and wear High strength Long term biocompatibility	Expensive Quite difficult to machine Stress shielding effect High Modulus Biological toxicity due to Co, Cr and Ni ions release	Shorter term implants-Bone plates and wires, Total hip replacements (THR)-Stem or hard-on-hard bearing system
<i>Ti alloys</i>	Excellent resistance to corrosion Lower Modulus Stronger than stainless steels Light weight Biocompatible	Poor wear resistance Poor bending ductility Expensive	Fracture Fixation plates, Fasteners, nails, rods, screws and wires, Femoral hip stems, Total Joint Replacement (TJR) arthroplasty-hips and knees

reactions causing toxicity. The major factor to be considered in this mechanism is how readily the ion particles combine with the protein biomolecules. For metals like Ti, Zr, Ne, Mg and tantalum when the ions are released, they react immediately with available OH^- groups and anions to form ion oxides and salt crystals in the body. So, the ions from these materials are not free to combine with the protein biomolecules to precipitate the inflammatory adverse reaction causing toxicity. Whereas ions of cobalt, chromium and nickel do not combine with anions or any other hydroxyl groups and remain free for long time and gets attached with protein biomolecules to cause inflammatory adverse reaction and toxicity ([Table 4](#)).

Metals Used for Biomedical Applications

Stainless Steel

Stainless steel can be easily cast into different shapes and sizes and was indeed the first material to be used to fabricate artificial bone. Hatfield introduced 18/8 stainless steel in 1920 which was able to overcome the limitations such as lower corrosion resistance and mechanical strength ([Hatfield, 1931](#)). The rate of metal sensitivity and incidence of the implant failure were lesser than other stainless steel grades and with fewer post-surgical complications. The carbon content of the stainless steel (18/8) was reduced to limit the formation of chromium carbides causing toxic reaction (allergic). The chromium content above 12 wt% with Ni and Mo was used to reduce the carbon content ([Eliaz and Metoki, 2017](#)). Although nickel helps in increasing corrosion resistance, it also reduces biocompatibility ([Rushing et al., 2007](#)). Nickel causes allergic reaction when implanted in the body. So, the SS used for biomedical applications are called as conventional SS to avoid Ni. Nitrogen is used along with the alloying elements to reduce the allergic reaction caused by nickel. The stainless steel without nickel are biocompatible and used for load bearing application and as arterial stent ([Ducheyne and Kohn, 1998](#)). The 316L stainless steel has low carbon content less than 0.03% and is widely used in bone fracture plates, screws, and nails in surgical practice for temporary purpose. The plates should be removed after the healing of the fracture. The 316L SS corrodes inside the body at highly stressed oxygen depleted environment. The lower carbon content helps to increase the corrosion resistant and ASTM has recommended 316L as a principal alloy for implant fabrication ([Driscoll, 2009](#)).

Cobalt Chromium Alloys

Compared to Ti Alloys, Co-based implants have higher wear resistance. In cases of hip joint replacements, where there is an excessive chance of wear between the femoral head and the bone or plate, cobalt based alloys are well suited ([Alvarado et al., 2003](#)). Co- based

Table 4 Summary of the pathophysiology and toxicology of various alloying elements

Element	Blood serum level	Daily allowance	Pathophysiology	Toxicology
<i>Essential Elements</i>				
Mg	17.7–25.8 mg/L	700 mg	Activator of many enzymes; co-regulator of protein synthesis and muscle contraction; stabilizer of DNA and RNA	Excessive Mg leads to nausea
Ca	36.8–39.8 mg/L	800 mg	More than 99% have structural functions in the skeleton; the solution Ca has signaling functions, including muscle contraction, blood clotting, cell function, etc.	Inhibit the intestinal absorption of other essential minerals
Fe	5000–17,600 mg/L	10–20 mg	Component of several metalloproteins; crucial in vital biochemical activities, i.e., oxygen sensing and transport	Iron toxicity gives rise to lesions in the gastrointestinal tract, shock and liver damage
<i>Essential Trace Elements</i>				
Zn	0.8–1.14 mg/L	15 mg	Trace element; appears in all enzyme classes; most Zn appears in muscle	Neurotoxic and hinders bone development at higher concentrations
Cu	4.51–8.32 mg/L	1–3 mg	Cu plays a vital role in the immune system; has beneficial effects on endothelial cell proliferation and has been reported to enhance antibacterial properties	Excessive Cu (> 1 mg/day) can cause neurodegenerative diseases, including Alzheimer's, Menkes and Wilson's diseases
Mn	< 0.0008 mg/L	4 mg	Activator of enzymes; Mn deficiency is related to osteoporosis, diabetes mellitus, and atherosclerosis	Excessive Mn results in neurotoxicity
<i>Other Elements</i>				
Sr	0.17 mg/L	2 mg	99% is located in bone; shows dose dependent metabolic effects on bone; low doses stimulate new bone formation	High doses induce skeletal abnormalities
Li	0.002–0.004 mg/L	0.2–0.6 mg	Used in the treatment of manic depressive psychoses	Plasma concentrations of 2 mM are associated with reduced kidney function and neurotoxicity, 4 mM may be fatal
Al	0.0021–0.0048 mg/L	–	–	Primarily accumulates in the bone and nervous systems; implicated in the pathogenesis of Alzheimer's disease; can cause muscle fiber damage; decreases osteoblast viability

alloys are used for orthopedic prosthesis due to their excellent corrosion resistance in chloride environment which could be attributed by the alloying elements added to it. They form a protective Co_2O_3 passivating layer thereby preventing the wear and corrosion. The most commonly use cobalt based alloy is Co-Cr-Mo due to its high strength and high ductility. With the addition of Nickel, the alloy CoNiCrMo also called as MP35N contains 35% Co and Ni, thereby demonstrating excellent corrosion resistance and high mechanical strength compared to cast Co-Cr alloy (Aherwar *et al.*, 2016). However, nickel is potentially toxic and use of CoCr-Ni-Mo is not recommended for applications concerning the biocompatibility. The Co-Cr alloy has high elastic modulus compared to Ti or Ti Alloys (Aherwar *et al.*, 2016; Li *et al.*, 2004). But Co-Cr has high elastic modulus compared to bone which leads to greater stress shielding effect when compared to Ti, Ti alloys or Mg Alloys (Nayak *et al.*, 2016). Compared to titanium or magnesium alloys, the osteointegration capacity and biocompatibility of Co-Cr is reduced. Li *et al.* (2014). Hence, in a clinical scenario that presents with a need for direct contact of the implant material and bone, Ti or Mg can be used (screws and pins). Co-Cr can be used in cases where there would be no interface with the bone (Rods in spinal fixation). In situations where Ti and Co-Cr Alloys are in close contact, there is shredding at the site of contact due to frictional load. The tissue near these materials experiences metallosis (Nayak *et al.*, 2016).

Titanium Matrix Composites

Titanium and its alloys are mainly used as implants in the field of orthopedics and dentistry. Besides implants, these biomaterials are also being used as surgical guides and tools. The main reasons for them to be an ideal material for biomedical applications can be attributed to their striking features such as biocompatibility, high strength, and good corrosion resistance (Faria *et al.*, 2008). Compared to stainless steel, titanium has a higher strength to weight ratio, which means that titanium is stronger but lighter.

Table 5 Elastic modulus of the cortical bone, commercially pure titanium (CP-Ti) and Ti6Al4V alloy

Material	Specification	Elastic modulus (GPa)
Bone	–	≤ 30
CP-Ti	ASTM F67 Grade 1	103–107
CP-Ti	ASTM F67 Grade 2	103–107
CP-Ti	ASTM F67 Grade 3	103–107
CP-Ti	ASTM F67 Grade 4	103–107
Ti6Al4V	ASTM F136 Grade 5	114–120

Abbreviation: GPa, GigaPascal.

Note: ASTM F136, 2013. Standard Specification for Wrought Titanium-6Aluminum-4Vanadium ELI (Extra Low Interstitial) Alloy for Surgical Implant Applications (UNS R56401). ASTM F, 1981. Standard Specification for Unalloyed Titanium for Surgical Implant Applications. American Society for Testing and Materials, Philadelphia, PA.

Possessing these favorable properties, titanium and its alloy's application are not just limited to the biomedical field, but have also gained significance in the aerospace, automotive, and marine industries.

When to be used in various parts of the body, it is important to understand the site and purpose of the implants. For example, as a load-bearing implant, hip or knee implant would require a stiffer biomaterial as compared to a heart stent. Besides, hip and knee have movable joints which would subject the implants to increased wear and tear. For these reasons, researchers are constantly focusing on developing new alloying materials to enhance their properties in terms of biocompatibility, stiffness, and corrosion resistance. One example is the replacement of commercially used pure titanium (CP-Ti) to Ti6Al4V (Ti64) to Ti-Nb-Zr (Silva *et al.*, 2004). The American Society for Testing and Materials (ASTM) has categorized these materials into different grades, some of which are used as surgical implants (ASTM F136, 2013; ASTM F, 1981). Others have also been researched for coating the metals to improved osseointegration (Morin *et al.*, 2017; Subramani *et al.*, 2016; Wong *et al.*, 2011; Zhang *et al.*, 2018a).

Despite medical acceptance, the stiffness of some of these materials is too high as compared to the human bone which causes bone stress-shielding. Moreover, the toxicity of vanadium, the alloying element, has raised concerns. Thus, it is in the interest of researchers to develop the ideal titanium-based biomaterial that are biocompatible and exhibit good mechanical properties and good corrosion resistance properties.

Titanium Matrix Composites (TMCs) are materials that consist of titanium or titanium alloys as the base material while the reinforcement can be another material like metal, ceramic or an organic compound (Table 5). TMCs are constantly developed for biomedical applications to reduce Young's modulus, enhance osseointegration and biocompatibility. Thus, it is important that materials used to form the TMCs are biocompatible. Niobium pentoxide (Nb_2O_5) is biocompatible and have been used to coat titanium alloy using a sol-gel technique that greatly improves its biocompatibility, bioactivity and corrosion resistance. In a study to improve its load-bearing strength and excellent biocompatibility, Li *et al.* fabricated a Ti-Nb $_2$ O $_5$ composite by using CP-Ti powder and reinforcing it with 2%, 3% or 4% Nb $_2$ O $_5$ particulates using a cold press (300 MPa) and sintering (1000°C) method (Moghaddam *et al.*, 2016). The biocompatibility assay showed that the osteoblast-like SaOS2 cells exhibited similar cell proliferation and variability to CP-Ti, suggesting that Ti-Nb $_2$ O $_5$ is not toxic and is biocompatible.

Diamond (D) was studied previously as a coating material for orthopedic implant materials due to its high hardness and low coefficient of friction, thus providing high wear resistance. Coated diamond films on titanium alloy implant showed that they are biocompatible and also promote osteogenesis while displaying high resistance to bacterial colonization and bioactivity at the molecular level. Using powder metallurgy, Guimaraes *et al.* combined CP-Ti powder with 2%, 5% or 10% (wt%) of diamond powder and compacted using a uniaxial pressing (100 MPa) and subsequently sintered (1250°C) the green part (Guimaraes *et al.*, 2017). Though the Ti-D composite exhibited increased stiffness, Ti-2D (2% D) had the best of physical and mechanical properties with an increase in porosity, which is favorable to osseointegration. In comparison to CP-Ti, Ti-2D was also biocompatible with better cell adhesion and proliferation of VERO cells.

Calcium phosphate (CaP) is a natural bone mineral. CaP is among the most widely used bio ceramics with excellent bio resorption and compatibility specific to enhance bone repair (Eliaz and Metoki, 2017). Most load-bearing implants are made of titanium and its alloys while some include the replacement of joints. Materials for such purposes are subjected to wear, resulting in the release of metal ions in the system. In 2016, Bandyopadhyay *et al.* fabricated a matrix of Ti-CaP and Ti64-CaP using laser-based additive manufacturing known as Laser Engineered Net Shaping (LENS) (Bandyopadhyay *et al.*, 2016). For the articulation of a load-bearing implant, they reported that both titanium matrix composite exhibited reduced wear rate while reporting an increase in strength and hardness.

Hydroxyapatite (HA) is an inorganic compound that is widely studied due to its biological importance to human bones and teeth. It also makes up 50% (vol%) of the human bones. Thus, HA is a biocompatible material. As HA stimulates bone ingrowth, HA-coated implants have enhanced osseointegration. One of the main concerns of HA-coated titanium is the reduced biocompatibility due to HA decomposition at high temperature (1400–1450°C) during the adhesion process like conventional pressing and sintering (Daugaard *et al.*, 2010). Other concerns include the detachment of the HA coating that may compromise osseointegration and subsequent implant loosening while detached particles may cause adverse effects on the surrounding tissue. Sintering Ti-HA powder at 800°C was able to produce a composite that was simple, cost-effective and biocompatible when assayed

Fig. 1 (a, d) Fluorescent scanning confocal reconstructed projections of live (green) and dead (red) stained adult human mesenchymal stem cells (hMSCs) with arrows indicating expansion of the cells into the corners of the 3DP channels at Day 14; and (b-c, e-f) low and high magnification SEM images of hMSCs on metallic (M) NiTi-6.7Nb micro-trusses after Day 1 and Day 14. Evidence of extracellular matrix (ECM) is present. Reproduced from Taylor, S.L., *et al.*, 2018. NiTi-Nb micro-trusses fabricated via extrusion-based 3D-printing of powders and transient-liquid-phase sintering. *Acta Biomaterialia* 76, 359–370.

with VERO or NIH3T3 cells (Comín *et al.*, 2017). The application of ceramics like ZrO_2 is seen to have very low wear rates and negligible ion release due to their low friction coefficient. These properties are especially important for load-bearing implants, such as implants at joints. As such, Zhang *et al.* developed a novel titanium composite by introducing ZrO_2 into Ti-24Nb-4Zr-8Sn (Ti2448) via the spark plasma sintering system for 10 min at 1150°C (Zhang *et al.*, 2018b). The resultant composite, Ti2448- ZrO_2 showed improved mechanical strength and corrosion resistance thus suggesting better biocompatibility than Ti2448.

Nitinol contains nickel and titanium that is biocompatible, and its attractive properties can be used in biomedical applications such as stents, dental devices, bone implants or actuators. In a study in 2018, Taylor *et al.* studied the NiTi-Nb composite with different percentages of Nb (0, 1.5, 3.1, 6.7 at%) (Taylor *et al.*, 2018). NiTi-6.7Nb had porosities of ~75%, which is similar to trabecular bone porosity. In addition, human mesenchymal stem cells (hMSC) exhibited viability, proliferation, and extracellular matrix deposition over 14 days in culture (Fig. 1).

Magnesium (Mg) is an abundant mineral in the body and is also naturally contained in many foods. Being a biocompatible element, Mg has also been studied as temporary implant material due to its biodegradable property. Mg-based alloys are investigated to fabricate implants to enhance its mechanical and biological properties. When Mg is introduced into Ti by powder metallurgy and spark plasma sintering, it has a lower elastic modulus. Upon implantation or in vitro simulated body fluid, Mg degrades over time, decreasing the elastic modulus further while inducing the formation of a calcium phosphatase layer (Liu *et al.*, 2015a). The bioactivity also improved as pores formed on the surface for cell attachment. Ti-35.3Nb-7.3Zr-5.7Ta (TNZT), a biocompatible titanium alloy, was used as a base material. It was reinforced with Fe (0–2 wt%) and Si (0–1 wt%) by electric arc melting (1400°C) and was subsequently forged. The final composite, TNZT-Fe-Si displayed lower elastic modulus of 65–85 GPa compared with Ti6Al4V (~115 GPa), but higher than TNZT (55 GPa) and cortical bone (10–30 GPa). Furthermore, MG63 cells cultured on the composites showed higher proliferation and collagen production than standard Ti6Al4V alloy (Kopova *et al.*, 2016).

Carbon nanotubes (CNT) have also been studied for their biocompatibility previously (Schrand *et al.*, 2007; Shim *et al.*, 2002; Smart *et al.*, 2006). To relieve the stress shielding effect for conventional bone implants, CNT was added in CP-Ti at 5 wt% and 10 wt%. The Ti-CNT exhibited an increased nano-hardness and elastic modulus as compared to CP-Ti. Moreover, the composite was biocompatible when assessed using 2 different cell lines; SAOS and human aortic smooth muscle cells (hASMC), on the DNA

damage and metabolic activity (Pavón *et al.*, 2019). Poly (methyl methacrylate) (PMMA) is biocompatible and has been widely used as medical devices, mainly known for contact lenses. Avolio *et al.* developed a new biomaterial by embedding CP-Ti nanoparticles as fillers in PMMA by solvent casting for tissue engineering purposes. Mechanical studies showed that nano fillers at 1 wt% was ideal. The composite was not toxic and did not affect the cell viability nor proliferation of the human mesenchymal stem cells (hMSC) (Avolio *et al.*, 2016).

Biodegradable Materials

Zinc Alloys

Zinc is a trace element, a significant catalyst for many enzymes, to maintain the structure and function of proteins and stabilizing the protein domains (Coleman, 1992). Most tissues are tolerant to zinc ions and they are being used as stents for bioresorbable metallic stents (Bowen *et al.*, 2016). The corrosion of zinc is influenced by the surrounding pH levels and anodic dissolution and cathodic reduction of dissolved oxygen (Bowen *et al.*, 2016). Zinc chloride and zinc oxide participates in the corrosion process at a pH of 7.3 (Bowen *et al.*, 2016). Zinc combined with Mg plays a significant role in corrosion rate, since it's not affected by the hydrogen gas evolution. Zinc is used as stents for arteries up to 6 months in rats showed no inflammatory response or thromboses. The stents showed tissue integration and partial degradation. Zinc along with magnesium is currently researched for plates and screws for fracture fixations. Zinc addition to magnesium influence the corrosion rate and mechanical property of the alloy (Heiden *et al.*, 2015). (Fig. 2).

Zinc based materials are studied for their application in cardiovascular and orthopedic applications (Table 6) (Fig. 3). The absorbable zinc materials when implanted in the body releases Zn^{2+} . The released Zn^{2+} comes in direct contact with the cells and tissues showing cellular and molecular responses. Cytotoxicity evaluation of biodegradable Zn-3Mg alloy toward normal human osteoblast cells and the cytotoxicity response of the osteoblast cells to 0.75 mg/ml Zn concentration was studied by Murni *et al.* (2015). The MC3T3 osteoblast cells did not cause any cytotoxicity. 153.8 μ M Zn concentration increased cell viability and showed no signs of cytotoxicity on pig pulmonary endothelial cells whereas increasing the concentration to 153.8 μ M inhibited cell viability and caused cell death (Murni *et al.*, 2015). Krones *et al.* (2005) showed that the concentration of Zn^{2+} from 80 to 120 μ M on human coronary artery endothelial cells showed decreased cell viability whereas concentrations below 80 μ M showed good cell viability. The morphology of the cells was affected by increased concentration. The cells were rounded and apoptosis of cells were found whereas less concentration of Zn showed well-formed flattened spindle morphology (Krones *et al.*, 2005).

Zn increased the proliferation, cell differentiation and osteogenic gene expression mechanism of human bone marrow stromal cells (Ma *et al.*, 2015; Zhu *et al.*, 2017). Zn has antibacterial efficacy on both gram-positive *S. aureus* and gram-negative *E. coli* organisms. They damage the bacterial cell membrane by binding with the bacterial DNA (Bakhsheshi-Rad *et al.*, 2017). Su *et al.* (2019) stated that there is a change in the cell viability and biocompatibility among the various zinc groups like ZnP, ZnO and Zn hydroxide. The cell adhesion on the surfaces of the groups showed well-formed cell fattened spindle cellular morphology for ZnP group whereas the other groups showed round apoptotic cell morphology. The in vitro cell viability of the pre-osteoblasts seeded directly on the samples showed increased cell viability for ZnP group compared to other groups. Interfacial Zinc Phosphate is the key to controlling biocompatibility of metallic zinc implants. Jin *et al.* (2018) combined zinc with magnesium and formed an alloying element for arterial biodegradation. The magnesium was added at concentration of 0.002%, 0.005% and 0.008%wt with the zinc. The in vivo biocompatibility of the alloy was done on SD rats for a period of 1–11 months. The results showed that the increase in concentration of magnesium showed trends of decreased biocompatibility. The histological studies showed increased macrophages and giant cells owing to increased inflammatory reactions near the implant site for 0.008% Mg (Jin *et al.*, 2018).

Wang *et al.* compared the osteosynthesis efficacy of novel zinc alloy with PLLA and titanium for canine mandibular fracture model. The micro CT images after 4 weeks implantation showed more external callus formation for the PLLA group compared to the zinc and titanium. After 12 and 24 weeks of implantation the calluses in all group decreased and calcification and remodeling of new bone was seen. The zinc alloy had more bone volume, total bone density and trabecular thickness compared to the titanium and PLLA (Wang *et al.*, 2019) (Fig. 2(a and b)).

Ren *et al.* (2019) evaluated the corrosion and biocompatibility of Zn-xMg-0.5Zr alloy for orthopedic application. In comparison to pure Zn, addition of Mg and Zr showed good grain refinement, improved tensile strength and corrosion resistance. With an increase in the magnesium concentration from 1.5 wt% the corrosion of the alloy increased and the cytocompatibility decreased. With the addition of 0.5% and 1% magnesium, the corrosion rate was less and the cytocompatibility also increased. Histological analysis after 90 days post-implantation of Zn-1Mg-0.5Zr compared with SUS304 on the subcutaneous muscle of SD rats showed healthy perimysium and muscle fibers. There was no signs of inflammatory reaction or necrotic tissues surrounding the implants for both the groups. The histological results showed that Zn with the addition of Mg and Zr in less concentration showed good biosafety and are suitable for biomedical applications (Ren *et al.*, 2019). The long-term implantation of zinc alloys combined with aluminum for 20 months in abdominal rat aorta showed increased activity of macrophage penetration. The macrophages were able to penetrate the thick corrosion layer that was formed around the implants. The pure zinc group showed delayed macrophage entry into the corrosion layer. This is due to low corrosion rate with greater fibrous encapsulation around the implant. The addition of aluminum to the zinc increased the macrophage activity due to the intergranular corrosion (Guillory *et al.*, 2019, 2016).

Iron Alloy

Among the metals used for biomedical application, iron has the lowest tendency to dissolve. The daily dose of iron is 10 mg. The corrosion of Fe is mediated by dissolved oxygen. There is a protective surface oxide layer formed with iron when exposed to physiological fluid and this attributes to the lower corrosion rate and prevents rapid degradation (Bowen *et al.*, 2016) (Fig. 4). There is no negative inflammatory response or cell toxicity or thromboses when Fe biodegradable stents were tested on pigs and rats (Bowen *et al.*, 2016) (Table 7). The Fe stents can be easily deployed into the arteries due to its high radial strength which allows it to be made into extremely thin structures. Although Fe has good corrosion resistance property, the production of iron oxide by-

Fig. 2 **a:** (A) Zinc alloy plate and screws, (B) PLLA plate and screws, (C) titanium alloy plate and screws. All implants are in the same dimensions. (D, E, F) Fixed mandibular bone fractures immediately after surgery for the three groups. **b:** Micro-CT three-dimensional reconstruction images (A zinc alloy, B polylactic acid, C titanium alloy) 4 weeks after the operation. The yellow highlighted area is the selected region of interest (3 mm wide and 7 mm high). In the micro-CT cross-sectional images 4 weeks post operation, PLLA I formed significantly more external calluses than the zinc alloys (D) and titanium alloys (F). (G, H) BV/TV and Tb. Th comparison of the three groups; the zinc alloy group is significantly higher than the PLLA group at 4 weeks post operation. Reproduced from (a and b) Wang, X., *et al.*, 2019. Fig. 3 Schematic showing the different Zn alloy combinations studied for biodegradable implant applications. Reproduced from Venezuela, J., Dargusch, M., 2019. The influence of alloying and fabrication techniques on the mechanical properties, biodegradability and biocompatibility of zinc: A comprehensive review. *Acta Biomaterialia* 87, 1–40.

products and influx of metallic ions into the surrounding tissues leads to cellular damage and cytotoxicity. The long-term overdose of iron [normal; 6–20 mg] may lead to cell damage by affecting the DNA, protein and lipid membrane. There is an increase in inflammation and free radicals leading to damage of lipid (Bowen *et al.*, 2016; Hong *et al.*, 2016). Iron implants may interfere with the MRI by heating up the implant due to the strong magnetic field. This leads to the change in the morphology of the implant and leaching of the iron particles. The displaced Fe particles exerts forces on the attached cells causing cell dragging and cytoskeletal changes and changing the intercellular signaling pathway. Further, iron used for load-bearing implant application may lead to stress shielding effect due to the differences in its properties and that of the natural bone. The slow degradation rate of iron reduces the tissue regeneration and prevents the forces transferring to the surrounding bone leading to stress shielding effect and failure of osteointegration (Ortolani *et al.*, 2016).

Liu *et al.* (2019) compared pure iron with iron bulk metallic glasses [Fe77m05P9C7.5B1.5] and investigated the antibacterial efficacy against *S. aureus* and *E. coli* and cytocompatibility of the composites with human umbilical vein endothelial cells [HUVE]. The composite inhibited bacterial growth mainly in *S. aureus* and without any changes in the *E. coli* and there were no signs of cytotoxicity to the HUVE cells (Liu *et al.*, 2019). Kraus *et al.* (2014) evaluated the degradation and toxicity of iron-based alloys [pure iron and Fe-10Mn-1Pd, Fe-21Mn-0.7C-1Pd] by implanting in the femur of SD rats over a time period of 52 weeks. The degradation process was very slow in all the groups with no significant difference between the groups. The oxygen transport around the implant was restricted by the dense layer of degradation products [Fe-oxides] around the implant surface. Although oxygen is necessary for the degradation of the iron, its availability away from the implant area is restricted by the degradation products surrounding the implants. There were no signs of local toxicity or clinically any abnormal changes in the tissues surrounding the implant site was noticed. The slow degradation rate of iron is still questionable to be used in temporary bulk implants (Kraus *et al.*, 2014). The cytocompatibility of Fe alloy [Fe-Mn-Cu] using MG63 cells showed increased cell viability at 72 h cell culture and showed flattened spindle elongated morphology without any signs of apoptosis (Mandal *et al.*, 2019).

Magnesium Alloys

Biodegradable metals are defined as any metals when placed within the body, has the ability to degrade completely with positive host response from the corrosion products thereby enhancing the tissue health without any material residue (Zheng *et al.*, 2014; Witte, 2010). Any metal can be considered biodegradable when it has a good corrosion rate within the body and the corrosion products released should be completely metabolized by the host body (Zheng *et al.*, 2014). There is a paradigm shift towards the use of biodegradable metals most importantly magnesium for their superior properties of preventing stress shielding effect. The use of magnesium dates back to 1878 when they were used for closure of blood vessels (Witte, 2010). Unlike the stainless steel commonly used for fracture plating, magnesium didn't show any signs of skin sensitization and had high tensile strength and elastic modulus nearly matching that of the natural bone (Witte and Eliezer, 2012). Magnesium is the fourth most abundant cation in the human body and acts as a cofactor for many enzymes (Witte and Eliezer, 2012). Magnesium is a light weight material with a density of 1.74 g/cm³. Although magnesium is considered to have higher superior properties, the corrosion rate of pure magnesium is high and needs addition of alloying element to control the corrosion rate. There are many factors which leads to the

Fig. 4 Properties and composites of iron based biomaterials. Reproduced from Bowen, P.K., *et al.*, 2016. Biodegradable metals for cardiovascular stents: From clinical concerns to recent Zn-alloys. *Advanced Healthcare Materials* 5 (10), 1121–1140. Zheng, Y., Gu, X., Witte, F., 2014. Biodegradable metals. *Materials Science and Engineering: R: Reports* 77, 1–34.

increased corrosion rate of any metal placed as an implant within the body. One main factor among them is the pH of the body fluids. In cases of trauma and infection, immediately after the placement of implant within the body tissues, the pH of the surrounding area drops to 5.3–5.6 (Ebenezer *et al.*, 2015). The drop in pH activates the infectious microorganisms surrounding the implant area and reduces the oxygen concentration around the implant causing cellular damage. The depleted oxygen environment and pH increases the corrosion of magnesium leading to more degradation of the metal. The most possible way to reduce the corrosion of pure magnesium is by the addition of suitable alloying elements, processing methods and coatings which reduces the initial implant corrosion thereby sustaining the initial drop in the pH and oxygen levels surrounding the implant area. The addition of suitable alloying element to magnesium reduces the corrosion rate and allows a balance in time needed to new tissue/bone regeneration (Table 8). In compared to the in vitro, in-vivo corrosion observed is lesser due to the adherence of proteins and inorganic deposits like calcium phosphates which leads to further reduction in the corrosion rate (Prasadh *et al.*, 2019a; Witte and Eliezer, 2012). The corrosion of magnesium ions from the implant is quickly removed by the blood serum and the kidneys. The extracellular fluids contain a constant magnesium concentration of 0.7–1.05 mM. With the presence of high serum levels of magnesium ion concentrations of up to 6–7 mM, it leads to paralysis of the muscles, respiratory distress and cardiac arrest (Witte and Eliezer, 2012). The corrosion products released from the degraded magnesium are digested by the macrophages and the giant cells. The engulfed macrophages and the giant cells release inflammatory cytokines like IL-1 and IL-6 which further initiates the osteoclasts to begin the process of osteolysis (Lu *et al.*, 2002). Magnesium degrades releasing hydrogen gases which forms gas pockets when implanted in subcutaneous tissues, whereas no reports of gas pockets in intravascular stents were reported. This could be due to the fact that the diffusion and solubility coefficient of hydrogen gas released from the magnesium depends on the proteins, lipid content and glycosaminoglycans. The diffusion of hydrogen gas differs in stagnant and flowing fluids. That's the attributing factor of increased corrosion rates in an in vitro scenario compared to in vivo. In the further sections of this article we will be focusing on the various alloying elements added to the magnesium and how the elements affect the biocompatibility of the composites (Witte and Eliezer, 2012) (Table 9).

Classification of Mg alloying elements

Alloying elements of Mg can be categorized into five categories based on their characteristic features that affect the microstructure, mechanical properties, corrosion resistance, and biocompatibility of the Mg.

Bio-functional elements (Sr and Ca)

Sr has been reported as an osteoinductive element. It plays a key role by triggering the formation of new osteoblasts, thereby promoting rapid integration of the graft. Additionally, it is a biocompatible element that enhances the mechanical properties and the corrosion resistance of Mg alloys when the addition of Sr is $\leq 5\%$ (Li *et al.*, 2012).

Ca being the most abundant element in the human body is present in the form of the mineral HA in the skeleton. Studies have proved that any disturbance of Ca cation in the human body may possibly lead to severe pathological conditions. The additive

Table 7 Summary of animal tests for Fe-based biodegradable metals

Material	Animal model	Duration	Findings	References
Pure iron stent	Rabbits, descending aorta	6–18 months	No thrombogenicity, no significant neointimal proliferation and systemic toxicity, faster degradation at junctions of the stent; locally discoloration of intima	Peuster <i>et al.</i> (2001)
Pure iron stent	Porcine, descending aorta	360 days	Complete coverage of neointima after 14 d; accumulation of degradation product adjacent to the stent struts and within adventitia accompanied by macrophages; disintegration of struts after 1 year with large portions of the stent residue; no sign of iron overload or iron-related toxicity	Peuster <i>et al.</i> (2006)
Pure iron stent	Porcine, coronary arteries	360 days	Locally discoloration of the vascular wall adjacent to the stent; degradation was evidenced at 28 d; similar vessel parameters to Co–Cr stent	Waksman <i>et al.</i> (2008)
Pure iron stent	Rat, artery lumen or artery matrix	1–9 months	Fe wire experienced substantial corrosion within artery matrix, whereas experienced minimal bio corrosion in blood-contacting environment	Pierson <i>et al.</i> (2012)
Nitrided iron stent	Porcine, iliac arteries	12 months	A nearly intact endothelial cells layer formed on the stented vessel wall; a decreased inflammation scoring, ~30% loss of in-stent luminal diameter, ~47% reduced strut thickness and corrosion product accumulation 12 months post implantation	Feng <i>et al.</i> (2013)

Note: Bowen, P.K., *et al.*, 2016. Biodegradable metals for cardiovascular stents: From clinical concerns to recent Zn-alloys. *Advanced Healthcare Materials* 5 (10), 1121–1140.

amounts of Ca to Mg alloys should be limited to less than 1% because higher Ca content in Mg alloys will lead to the formation of a large volume of the secondary phase of Mg_2Ca , which diminishes the corrosion resistance of Mg alloys (Li *et al.*, 2010, 2008).

Biocompatible element (Zr)

Zr is established as an effective alloying element that improves the corrosion resistance and grain refinement of Mg alloys. This is essential in order to decrease the degradation rate of Mg alloys in vivo. Recent studies have indicated that the addition of Zr to Mg alloys should be limited to less than 5% (Li *et al.*, 2012).

Essential trace elements (Mn and Zn)

Mn and Zn are essential trace elements for the human body and they are usually used in Mg–Al alloys such as in AZ series. When it comes to using Mn and Zn as Mg alloying elements, concentration control has often been a significant consideration. Unfortunately, literature lacks any systematic research to define the concentration limits of Mn and Zn in biodegradable Mg alloys. Further studies are needed to elucidate the optimal concentrations of Mn and Zn in Mg alloys for a favorable combination of corrosion resistance, mechanical properties, biocompatibility and biodegradability that can be acceptable for load-bearing implant applications.

Toxic elements which should be avoided (Al, Li, Ce, Er, La, and Nd)

The accumulation of Al in the human body may be responsible for causing a disease process (Izumi *et al.*, 2009; Cases, 2005; Hirano *et al.*, 1993). Li is toxic to humans. A dose of 10 mg/L Li in the serum of humans could induce bipolar disorder, and with 20 mg/L Li in the serum there is a risk of death (Ferrante *et al.*, 2013). La (Feyerabend *et al.*, 2010; Tsuda *et al.*, 1992) and Ce (Bruce *et al.*, 1963; Scalbert *et al.*, 2002) showed a lower value of LD_{50} . Understanding the toxicological effects of Ce on the human body, it is seen that Ce tends to accumulate primarily in the bone, liver, heart and lung (Chen *et al.*, 2005). Nd being a light REE exhibits similar toxicity to La and Ce. Although Er belongs to the group of REEs with large ionic radii, it is moderately to highly toxic, causing writhing, ataxia, labored respiration, walking on the toes with arched back, and sedation (Ding *et al.*, 2014).

Results on the biocompatibility of Gd and Y are still inconclusive

Current studies demonstrates that Gd (Feyerabend *et al.*, 2010) and Y (Pogosova *et al.*, 2013) are potential alloying elements in Mg alloys for biomedical applications. Nevertheless, the toxicity of Gd appeared to be apparent as even 1% Gd chloride caused perinuclear vacuolization of the parenchymal cells of the liver, besides affecting bone quality and health (Darrach *et al.*, 2009). Y showed obvious toxicity due to the increased blood eosinocyte levels thereby causing eosinophil infiltration in the submucosa (Bruce *et al.*, 1963). Further research in the future can possibly reveal the effects of Gd and Y, outlining their concentrations on the microstructure, mechanical properties, corrosion resistance and biocompatibility of Mg alloys.

This classification provides suggestions for the early stage of implant development and the selection of alloying elements. Interestingly, some of the alleged “toxic elements” used in alloying, such as Li, La, Ce and Nd, have been successfully applied in commercial Mg alloys for biomedical applications (Waksman *et al.*, 2006). Despite the perceived toxicity of these elements, they are still employed judiciously for various biomedical applications. There is no evident harmful or beneficial substance, and even pure water can kill at a sufficiently high dose (Yuen and Ip, 2010). Thus, the dose of alloying elements determines the associated toxicity levels. For instance, despite Sr being classified as a bio-functional element, excessive addition of Sr in Mg alloys deteriorates the corrosion resistance, and impairs the biocompatibility.

Concern of biocompatibility in alloying of Mg

An orthopedic Mg implant is characterized as any matter, structure, or surface that interacts with biological tissues, and is required to possess biomechanical compatibility with natural bone, an appropriate corrosion rate (i.e., degradation rate) to maintain mechanical integrity during healing and excellent biocompatibility making it harmless to host tissues. Following implantation, the Mg alloy implant would directly come in contact with the organics or tissues. In an in-vivo scenario, the reaction between metals and a physiological environment such as proteins, cations and anions triggers the degradation of Mg alloys. The biocompatibility of Mg alloys is determined by the alloying elements in most cases. Hence it is significant to select the Mg alloying elements that are essential for the human body. Approximately 96% of the human body is comprised of oxygen, carbon, hydrogen and nitrogen, which are present in the form of water and proteins (Chen *et al.*, 2012). The remainder 4% largely exists either in the bone and tooth as minerals (Ca, Mg and P) or in the body fluid and blood as electrolytes (Na, K and Cl), which are considered to be macro elements (VanPutte *et al.*, 2016). Besides the macro elements, lower concentrations of barium, beryllium, boron, cesium, chromium, cobalt, copper, iodine, iron, lithium, molybdenum, nickel, selenium, strontium, tungsten and zinc also exists. These elements are referred to as trace elements (Chen *et al.*, 2012). Researchers have revealed the potential of Ca, Li, Sr and Zn as alloying elements for biodegradable Mg alloys.

Recent researches have attempted to elucidate the biological performance of Mg alloys when combined with these elements or with other traditionally used alloying elements such as Al, Mn and Zr, and REEs to be employed for biodegradable Mg alloy implant materials. Certain significant pre-requisites of an ideal Mg implant material includes their ability to be non-toxic and not cause any inflammatory and immunogenic responses. The Mg alloys should have minimal deleterious effects and these should be short term as much as possible. Nevertheless, in the actual application process, this ideal situation is not always attained. However, it is often a mandate to ensure that the composition of Mg alloys does not impose a significant hazard to the human body.

The effect of commonly used alloying elements

Alloying and surface treatments of magnesium used for biomedical applications is the most suitable method to corrosion rate until the tissue/bone is completely regenerated. The most commonly used nutrient elements used for alloying with magnesium are zinc (Zn), calcium (Ca), manganese (Mn) and strontium (Sr). Al possesses certain excellent effects on the refining of the microstructure and enhancement of corrosion resistance, which makes it the most widely used element for Mg alloys (such as AZ21, AZ91D and AZ31). However, medical research has revealed that accumulation of Al in the brain may harm the intelligence and cause neuropathological relevant issues (Krewski *et al.*, 2007), and can also account for the development of Alzheimer's disease (Carter, 2010). It is understood that with increasing age, Al tends to accumulate in the tissues, and the increasing concentration of Al eventually results in the aggregation of β -amyloid, a factor leading to the formation of pathologic lesions in Alzheimer's disease (Krewski *et al.*, 2007). Furthermore, Al has a significant impact on immunology, and studies have shown that the vaccines containing Al may lead to lymphocyte and inconspicuous muscle fiber damage (Cases, 2005). The total body burden of Al in healthy adults is 30–50 mg and the safe dose of Al containing medications can permit a much larger amount of Al than in

Table 11 Summary of animal tests and clinical trial of Mg alloy stent within blood vessels

Usage	Alloy	Biocompatibility	Degradation	References
Animal test	AE21 stent (pig, coronary artery)	40% loss of perfused lumen diameter between days 10 and 35 due to neointima formation; a 25% re-enlargement between days 35 and 56 caused by vascular remodeling	Linearly degradation ~ 89 d	Laing (1979)
	WE43 stent (minipig, coronary artery)	The struts are covered by neointima after 6 d; higher minimal lumen diameter on week 4 and 12 than the 316L stent group	~ 98 d	Ma <i>et al.</i> (2016)
	AMS (preterm baby, pulmonary artery)	Normal serum Mg level on 72 h, persisted left lung perfusion throughout the 4-month follow-up, clinical tolerable to baby	~ 5 months	Witte (2010)
Pediatric use	AMS (newborn baby, aortic arch)	Restenosis after 3 weeks implantation; implantation of a 2nd AMS; the stent struts were substituted by a jelly-like CaPO ₄ compound and fibrotic structure; flexible stent segment	–	McBride <i>et al.</i> (1989)
	AMS (2-month-old girl, aorto-pulmonary collateral)	Restenosis after 4 months implantation of AMS	–	Mayer (1931)
	AMS (20 patients, 23 stents, lower limb vascular)	A low immediate elastic recoil; 89.5% primary clinical patency after 3 months and 72.4% after 24 months; no blood or vessel toxicity	–	Song and Shayan (1998)
	AMS INSIGHT (60 patients, 74 stents, lower limb vascular)	Lower angiographic patency rate 31.8% for AMS treatment and comparable complication rate 5% with PTA treatment (patency 58%, complication rate 5.3%)	~ 4 months	Zhang <i>et al.</i> (2010)
Clinical trial	PROGRESS-AMS (63 patients, 71 stents, 8 centers, coronary artery)	Restenosis caused by stent recoil and intra- and extra-stent neointima at 4 months; the neointima decreased after over 12 months; No myocardial Infarction, subacute or late thrombosis, or death occurred	~ 4 months	Li <i>et al.</i> (2008), Xin <i>et al.</i> (2008)
	BIOSOLVE-I DREAMS (46 patients, two cohorts, cohort 1 for 6 months and 2 for 12 months)	7% rate of target lesion failure, 4.7% revascularization rate, no significant change of vasoreactivity between 6 and 12 months, reduced lumen loss from 6 month to 12 month, no death and no thrombosis	–	Haude <i>et al.</i> (2013)

Note: Zheng, Y., Gu, X., Witte, F., 2014. Biodegradable metals. Materials Science and Engineering: R: Reports 77, 1–34.

the diet, possibly as high as 12–71 mg kg^{−1} per day (Keith *et al.*, 2008). Literature demonstrates that the exceeding doses have various adverse effects in humans (Verstraeten *et al.*, 2008) (Tables 10 and 11).

Ca is the most abundant element in the human body, occurring in the form of Ca²⁺ and present as the mineral HA in the skeleton (Renkema *et al.*, 2008). Its addition to the Mg alloys is useful for biomedical applications. Results of one study showed that the degradation media of the Mg alloys over 6 days had no influence on cell viability whenever they employed an Mg–Ca alloy, owing to the excellent biocompatibility rendered by the less than 1.2% of Ca used in the alloy (Feser *et al.*, 2011). Jung *et al.* (2012) reported that needle-type calcium phosphates similar to HA formed at the interface of Ca-containing implants and biological tissue, providing a progressive biological environment for bone mineralization. Ca also plays a crucial role in bone disease and soft tissue calcification (Viriyavejikul *et al.*, 2007). Normally, Ca is present at a level of 0.919–0.993 mg/L in the normal blood serum (Johnson and Riechmann, 1968). The recommended Ca dietary allowance for adults is approximately 1000 mg per day (Ilich and Kerstetter, 2000). Any disturbance of Ca cation in the human body may lead to severe pathological conditions, such as hypercalcemia and hypocalcaemia (Lopez *et al.*, 2009). Furthermore, an excess of calcium and phosphate absorption results in vascular calcifications, an important contributing factor for cardiovascular disease associated with kidney disease (Toussaint and Kerr, 2007). Another concern of Mg–Ca alloys is the formation of an insoluble corrosion product on the surface. Kirkland *et al.* pointed out that the insoluble “chalk like” product could become problematic to the human body if large amounts are formed (Kirkland *et al.*, 2010).

Alloying of calcium along with magnesium forms a stable intermetallic phase and improve the strength, creep properties and modifies the microstructure thereby reducing the corrosion. The acceptable level of biocompatibility when calcium added to magnesium is <= 1 wt%. Makkar *et al.* (2018) studied the in vitro degradation and in vivo biocompatibility of Mg–X Ca (X= 0.5 or 5 wt%) in rabbit model. The addition of 0.5 Ca showed increased new bone formation and biocompatibility compared to Mg–5Ca alloy. The initial corrosion rate was high for Mg–5Ca alloy compared to Mg–0.5Ca alloy. This could be the attributing fact in the biocompatibility of both the alloys (Makkar *et al.*, 2018). Li *et al.* (2008) combined Ca with magnesium with Ca content from 1 to 20 wt%. The alloy of Ca content was brittle when increased from 5 to 20 wt%. The cytotoxicity evaluation using L929 fibroblast cells showed Mg–1Ca alloys didn’t not show any signs of toxicity and the cell viability was also increased. Whereas by increasing the Ca concentration from 5 to 20 wt% showed reduced cell viability and increased cytotoxicity (Li *et al.*, 2008). Mohamed *et al.* (2019) studied the in vitro degradation and cytotoxicity of 0.8 wt% Ca addition to Mg. The addition of 0.8 Ca to Mg showed a reduced corrosion rate compared to pure Mg and there was slight increase in the cell proliferation and cell viability compared to pure Mg when tested on HEK 293 human derived stem cells. This is attributed to the fact that the formation of

Fig. 5 SEM micrographs of (a) Mg/1Ca, (b) Mg/5Ca and (c) Mg/10Ca composite samples after 72 h immersion in DMEM. Reproduced from Zheng, Y., *et al.*, 2010. In vitro degradation and cytotoxicity of Mg/Ca composites produced by powder metallurgy. *Acta Biomaterialia* 6 (5), 1783–1791.

carbonated hydroxyapatite crystals on the implant surfaces mimics the bone apatite crystal and reduces corrosion rate (Mohamed *et al.*, 2019). Liu *et al.* (2015b) evaluated the biosafety and corrosion products of Mg-30% Ca alloys. Black powder precipitate particles and small amount of white precipitate particles were released when the Mg-30%Ca degraded. The black powder particles were made of outer shell of Mg (OH)₂, MgO and Mg/Ca mixture. The cell cytotoxicity studies done with L929 fibroblasts showed no signs of cytotoxicity and cell apoptosis. The morphology of the cells was flattened and spindle shape (Liu *et al.*, 2015b). Zheng *et al.* (2010) studied the cytotoxicity of Mg/Ca alloy produced by powder metallurgy against L929 fibroblast cells. The cell viability results on day 1 and day 4 showed no significant difference between the 1, 5 and 10 Ca concentrations whereas on day 4 the Mg-10 Ca showed 40% decrease in cell viability and change in the morphology of cells from flat spindle to round cells. Cell cytotoxicity could be due to the increase in corrosion rate of Mg-10 Ca alloys compared to 1 Ca and 5 Ca alloys (Zheng *et al.*, 2010) (Fig. 5).

The discovery of Li drew a lot of attention for its characteristic of being potential alloying element. Li inhibits the functioning of multiple enzymes in the body thereby striking numerous effects in humans and in other organisms (Yang and Xi, 2016). (Giles and Bannigan, 2006) reported that Li was a teratogenic hazard to the cardiovascular system of the human body, following his study on mice and rats where they observed their ability to produce skeletal and craniofacial defects following the administration of Li. Aral and Vecchio-Sadus (2008) investigated the toxicity of Li to humans and found that doses of Li (10 mg/L in serum) in humans induced bipolar disorder, and at 20 mg/L Li in the serum there is a risk of death. These studies further demonstrate the specific toxicity of Li presenting with several features such as acute abnormalities from Li poisoning and chronic changes such as nephrogenic diabetes insipidus, epithelial cell disease, and chronic kidney disease.

Mn is an essential trace element for physiological processes, and it is a necessary element for the immune system and a variety of enzymes (Erikson *et al.*, 2005). However, Mn toxicity, such as cytotoxicity and neurotoxicity, has also been reported (Ding *et al.*, 2014; Erikson *et al.*, 2005; Ding *et al.*, 2011). Ding *et al.* (2011) assessed the cytotoxicity of Mn on sensory hair cells, auditory nerve fibers and spiral ganglion neurons in three rats isolated from birth. The results showed that the sensory hair cells were vulnerable to Mn toxicity. Disservice was observed with Mn absorption as low as 10 µM. Preponderant clinical and basic research concerning the toxic actions of Mn has primarily focused on central nervous system effects (Ding *et al.*, 2011). Data from a recent report showed that the abnormal verbal and visual memory functions of a 10 year old boy were aggravated with excessive exposure to well water containing a modest level of Mn (Woolf *et al.*, 2002). Additionally, it was found that the neurotoxicity also presented on

Fig. 6 Histological thin slides of ZX50 (a–d) and WZ21 (e–h) pins in a Lévai-Laczko staining. WZ21 represents the positive properties of Mg alloys by enhancing new bone formations around the implant. Even in the case of massive callus formation and release of high amounts of gas (a) the bone shows no permanent harming. Reproduced from Kraus, T., *et al.*, 2012. Magnesium alloys for temporary implants in osteosynthesis: In vivo studies of their degradation and interaction with bone. *Acta Biomaterialia* 8 (3), 1230–1238.

the induction factor of a disease with similar properties to those of Parkinson's disease (Bock *et al.*, 2008). Considering these findings for the toxicity of Mn, one has to take significant precautionary measures when using Mn as the alloying element in Mg alloys for biomedical applications.

Zn is also a trace element in the human body and a co-factor for optional enzymes in bone and cartilage (Brandão-Neto *et al.*, 1995). According to the U.S. Department of Health and Human Services, the recommended dietary allowance for Zn is 11 mg per day for men and 8 mg per day for women, where the corresponding burden of Zn is approximately 0.16 mg kg^{-1} per day for men and 0.13 mg kg^{-1} per day for women (Roney *et al.*, 2006). Various studies have revealed the negative consequences of an overdose of Zn intake on growth, development and health (Gürsel *et al.*, 2012; Kailerich *et al.*, 1980; Lastra *et al.*, 2001; Weigand and Boesch-Saadatmandi, 2012). It has been shown that the divalent metal can also lead to neurological disorders (Brandão-Neto *et al.*, 1995; Fosmire, 1990). Zn cation acts as a mediated inhibitor of neurotrophins, and can even lead to cell death (Isabel Post *et al.*, 2008). Hence an accumulation of Zn in the human body may induce embryonic motor neuron death and thereby affect mature motor neurons (Isabel Post *et al.*, 2008). Thus, a normal Zn concentration is essential to maintain body health. In contrast, when a large amount of Zn was implanted into the body in the form of an alloying element in Mg alloys, the toxicity could be seen as possibly impairing the immune function (Fosmire, 1990). Thus, it is highly essential to understand the possible complications of using these alloys with Zn, and taking measures to control the concentration of the alloying element to be added in the Mg alloys.

Chen *et al.* (2011) compared the in vitro and in vivo biocompatibility of Mg-Zn alloy with Polylactic acid [PLLA] for orthopedic applications. The cell results showed improved cell attachment, mineralization and osteogenic gene expression for Mg-Zn alloys compared to PLLA. The gene expression for collagen1 was more for Mg-Zn alloy. The in vivo implantation of the samples in the femoral bone marrow cavity of rabbits after 12 weeks implantation showed more new bone formation for Mg-alloy compared to PLLA (Chen *et al.*, 2011).

Kraus *et al.* (2012) compared the in vivo degradation and osteosynthesis of magnesium pins implanted in the femoral region of SD rats made of two different alloys, ZX50 and WZ21. The results were evaluated after implantation of 4 weeks to 24 weeks. The results showed that ZX50 pins showed faster degradation with large amount of hydrogen gas volumes at 4 week there were signs of inflammation around the implants and callus formation and new bone growth was slow. Whereas WZ21 pins showed gradual degradation and less hydrogen gas volumes and the formation of new bone was fast and there was no harm in bone regeneration. The WZ21 pins showed excellent biocompatibility with no signs of inflammation (Kraus *et al.*, 2012) (Fig. 6). Ding *et al.* (2019)

Fig. 7 Clip occluded carotid blood vessels of rats showing no blood leakage post-surgery. Reproduced from Ding, P., *et al.*, 2019. In vitro and in vivo biocompatibility of Mg–Zn–Ca alloy operative clip. *Bioactive Materials* 4, 236–244.

used Mg–3Zn–0.2Ca alloy for artificial clips for ligating the carotid artery in SD rats. There was no blood leakage after post-surgery and there were no signs of inflammation during clip degradations and histological analysis and blood biochemical parameters showed no signs of inflammation. The in vitro analysis on L929 showed no cell toxicity (Ding *et al.*, 2019) (Fig. 7).

Wong *et al.* (2019) compared the osteogenic capacity and biocompatibility of Mg–Zn–Ca bulk metallic glasses with titanium alloy and PLLA. There were 80% cell survival rates for all the groups in lower concentrations of the extract media. The Mg₆₀Zn₃₅Ca₅ BMGC showed excellent biocompatibility compared to the Ti and PLLA when implanted in the rabbit femur for 24 weeks. The magnesium alloy showed more new bone formation compared to the other groups and less inflammatory cells. There was very limited bone formation observed in the PLLA group (Wong *et al.*, 2019). The use of Zr in Mg alloys had been reported by few studies, as an effective alloying element to improve corrosion resistance and grain refinement (Gu *et al.*, 2011a; Huan *et al.*, 2010). A recent study on the biocompatibility of Mg–Zr–Sr alloys showed that Mg alloys with an addition of Zr up to 5% exhibited excellent biocompatibility and no adverse effect was observed after implantation into rabbits (Li *et al.*, 2012). The good biocompatibility of Zr in Mg alloys was supported by another study on the Mg–Zr–Ca alloys, which indicated that an Mg alloy with an addition of 1% Zr and 1% Ca exhibited promising compressive strength, good corrosion resistance and excellent biocompatibility (Li *et al.*, 2011; Zhou *et al.*, 2013). Yamamoto *et al.* (1998) investigated the cytotoxic evaluation of 43 metal salts including ZrCl₄ using murine fibroblasts and osteoblastic cells and found that Zr⁴⁺ had relatively low cytotoxicity, although it was reported that a high dose through oral administration (2250 mg kg^{−1} per day) of an aqueous solution of Zr oxychloride to mice induced chromosomal abnormalities in bone marrow cells (Yamamoto *et al.*, 1998). In another study by Delongea *et al.* (1983), it was shown that Zr oxychloride did not influence the growth curve after repeated administration of a dose of 230 mg kg^{−1} per day, and Zr oxide has been found to be non-toxic in animal studies using mice and rats. The aforementioned findings indicate that Zr is promising in alloying biodegradable Mg alloys, nevertheless the fact that the biocompatibility of Zr depends on the applied dosage and Zr ions formed in the usage mandates further scrutiny (Delongea *et al.*, 1983).

Currently, researchers are trying to pursue better biocompatible elements to replace traditional, less biocompatible alloying elements in Mg alloys such as Al, Zn, Mn, etc, so as to develop new implants with improved biocompatibility. It has been reported that Sr can reanimate bone cells and benefit postmenopausal osteoporosis as it can increase bone formation (Atkins *et al.*, 2009; Marie, 2005; Naveau, 2004; Nielsen, 2004). Sr is a plant growth stimulant, possessing similar functions to Ca. Leveraging these advantages, Sr has been introduced into Mg alloys for biomedical applications. The biocompatibilities of binary Mg–Sr alloys with various amounts of Sr content were studied in vitro and in vivo (Bornapour *et al.*, 2013). An Mg alloy with the addition of 2% Sr showed promoted bone mineralization without inducing any significant adverse effects. Novel Mg–Zr–Sr alloys with improved corrosion resistance, mechanical properties and biocompatibility have been successfully manufactured and investigated in vivo and in vitro (Li *et al.*, 2012). The findings have concluded that the addition of Sr in Mg alloys leads to an improvement of in vivo biocompatibility, especially for the promotion of bone formation. In his study, Bornapour *et al.* (2013), showed that a Sr-substituted HA layer, known to improve cell growth and tissue healing around bone implants, presented at the interface between the alloy matrix and the corrosion products, after implantation of the binary Mg–Sr alloys into a rabbit.

Rare Earth Elements (REEs)

Current literature showcases numerous desirable advantages of REEs in Mg alloys, namely improved corrosion resistance and electrochemical behavior, and enhanced mechanical properties (Al-Samman and Li, 2011; Bayani and Saebnoori, 2009; Birbilis *et al.*, 2011). In most cases, standard Mg–REE alloys contain more alloying elements than their designations (Al-Samman and Li,

2011). Almost any REE-containing Mg alloy contains more than one trace REE, such as LAE (containing Li, Al and REEs) and WE (containing Y and other REEs) (Bayani and Saebnoori, 2009). It is further understood that the in-vivo degradation directly links the alloying elements of Mg alloys to the released metal ions and the corrosion products. The effects of REEs on the biological behavior of Mg alloys are crucial in implant applications and should be investigated thoroughly.

Until today, REEs-containing Mg alloys are the most successful of the developed Mg alloys for biomedical applications. For instance, WE43 has been successfully used in biomedical application. Once an Mg alloy is implanted in vivo, the alloying elements come into direct contact with cells and eventually react with the tissues. The physical and chemical properties of the elements well as the ionic size of alloying elements determines whether an element is retained by the cells or whether the element triggers a reaction. Thus, cell culture in vitro seems to be an effective experimental approach to determine the impacts produced by the alloying element. The short-term effects on various cells by REEs such as Y, Nd, Dy, Pr, Gd, La, Ce and Eu were studied in detail by Feyerabend *et al.* (2010) suggested that La and Ce displayed the poorest biocompatibility with the highest cytotoxicity on cells, whereas the highly soluble Dy and Gd seem to be more suitable. According to Nakamura *et al.* (1997) REEs can be chemically classified into three groups on the basis of their ionic radii: (1) light REEs: La, Ce and Pr, (2) medium REEs: Nd, Pm, Sm, Eu and Gd, and (3) heavy REEs: Tb, Dy, Ho, Er, Tm and Yb. The light REEs, Ce and Pr, usually induce severe hepatotoxicity, including symptoms of fatty liver and jaundice; medium REEs are mainly distributed into the spleen and lungs (Nakamura *et al.*, 1997). Longerich *et al.* (1991) investigated the effect of Y and Ce on the behavior of humans. His findings indicated that concentrations of Y and Ce in the drinking water of mothers with neural tube defect infants were higher than in the mothers of normal infants, indicating that the absorption of REEs is not only dependent on the concentration but also the size of the elements. Basar *et al.* (2010) investigated the biocompatibility of HA doped with Y^{3+} (2.5, 5 and 7.5 mol%) and F^{-} (2.5 mol%) ions based on the cellular response of the control group with pure HA and found that HA doped with 2.5 mol% Y^{3+} had the highest cell density compared with other Y-containing HA. The cell proliferation on 2.5 Y-HA was close to that of the control group. Loos *et al.* (2007) investigated the biocompatibilities of an absorbable Mg stent with Y and some REE additives in vivo and in vitro. He demonstrated that Mg alloys without Al but containing small amounts of Y and REEs would be appropriate for biomedical applications. All the above studies indicate that Y is a particularly disputed alloying element, and it is essential to further investigate the effect of the addition of Y in Mg alloys on biocompatibility. Besides cell culture studies, literature presents other studies that tested the toxicity of REEs. These studies that were performed on small animals chiefly involved the administration of REE-containing salts such as chloride REEs or nitrate REEs via intravenous injection, inhalation and orally (Kawagoe *et al.*, 2005). Tsuda *et al.* (1992, 1995) conducted a series of studies on the short-term effects of elements La, Y and Eu on rats fed with hydrated chloride. By comparing the responses of these three REEs with different oral doses of 0, 40, 200 and 1000 mg kg^{-1} for 28 successive days, results indicated that the biological effects of Y were very similar to those of La except for the accumulating patterns and volumes, while Eu showed an obvious irritation effect as hyperkeratosis of the forestomach and eosinocyte infiltration of stomach submucosa were found in both males and females receiving a dose of 1000 mg kg^{-1} $EuCl_3 \cdot 6H_2O$ (Tsuda *et al.*, 1992, 1995).

Magnesium Metal Matrix Composites

Magnesium based composites are currently being investigated for possible use in human body as temporary implants. Literature search has shown that magnesium based composites exhibit improved mechanical strength, superior grain refinement and reduced corrosion rates (Tables 8 and 12). Most of the reinforcement added to magnesium alloys have proven to be biocompatible and used for biomedical applications. The bioactive and bioinert reinforcements like Al_2O_3 , ZrO_2 , HAp, SiO_2 , β -TCP and bio glass have been utilized. To note that ceramics used for bio-applications are termed as bio-ceramics. The bio-ceramics are traditionally categorized into three groups: bioactive, biodegradable and biocompatible ceramics.

The calcium phosphate particles (CPP) which resembles the natural bone composites are added to the magnesium for use in biomedical and orthopedic applications. The calcium phosphate particle are osteoconductive and reacts with the physiological body fluids and helps in new bone formation (Song *et al.*, 2009; Wang *et al.*, 2008). The calcium phosphate particles reduce the degradation rate in physiological fluids and release the degradation products like Ca^{2+} , HPO_4^{2-} and PO_4^{3-} (Zheng *et al.*, 2010). The reinforcement of calcium phosphate to magnesium alloy showed decreased degradation rate and increased mechanical strength (Goh *et al.*, 2005; Habibnejad-Korayem *et al.*, 2009; Zhong *et al.*, 2007).

Magnesium - HAp composites have been used for various biomedical applications. Gu *et al.* reinforced Mg with various amounts of HAp (10 wt%, 20 wt%, 30 wt%) and studied the corrosion and cytotoxicity of the composites (Gu *et al.*, 2011b, 2010). The addition of 10 wt% HAp increased the tensile strength and showed less corrosion rates when compared to composites with higher amounts of HAp (20 and 30 wt%). The cytotoxicity of L929 cells showed increased cell proliferation and cell viability for 10 wt% compared to other concentrations (Gu *et al.*, 2011b, 2010). Cui *et al.* (2019) studied the effects of HAp reinforcement on Mg-2.5 Zn alloy for the mechanical strength, degradation and cytotoxicity. The composites were prepared by the spark plasma sintering. The results showed 49% decrease in corrosion rate and 43% increase in the mechanical strength. There was no noted cytotoxicity tested for L929 fibroblast cells (Cui *et al.*, 2019). Dubey *et al.* (2019) evaluated the mechanical integrity of Mg-HAp composites after in vitro exposure to the physiological solution (SBF). Mg-3Zn matrix was reinforced with 5 wt% HAp and immersed in SBF for 14 days. The results showed that the addition of 5 HAp retained the tensile integrity of the structures by 34% and 66% of compressive strength after 14 days immersion (Dubey *et al.*, 2019). Satish *et al.* Jaiswal *et al.* (2018) reinforced Mg-3 Zn matrix with 5 wt% HAp. Addition of 5 wt% increased the CYS by 23% and reduced the corrosion rate by 42%. HAp helps in apatite layer growth More apatite layer was observed with increasing period of immersion. Apatite layer formation on 5 wt% HA

Table 12 Mechanical and corrosion properties of magnesium matrix composites

Materials	Average size of reinforcement (nm)	Grain size (μm)	Microhardness (HV)	Tensile properties			Compression properties

Fig. 8 SEM micrograph of composite structures immersed for (a, b, c) 3 Days, (d, e, f) 7Days, (g, h, i) 14 Days, (j, k, l) 28 Days and (m, n, o) 56 Days. Reproduced from Jaiswal, S., *et al.*, 2018. Mechanical, corrosion and biocompatibility behaviour of Mg-3Zn-HA biodegradable composites for orthopaedic fixture accessories. *Journal of the Mechanical Behavior of Biomedical Materials* 78, 442–454.

composite was higher which is the reason for lower degradation rate of 5 wt% HA composite. The in vitro cytotoxic studies showed increased cell proliferation and well-formed spindle shape cell morphology (Jaiswal *et al.*, 2018) (Fig. 8). Ramya *et al.* (2018) studied that the addition of nano HAp particles to $Mg_{66}Zn_{30}Ca_4$ metallic glass and reported increased cell viability of MG63 osteoblast like cells, marginal improvement in the mechanical properties and increased corrosion resistance of the composite (Ramya *et al.*, 2018).

DMD-Disintegrated Melt Deposition, PM-Powder Metallurgy, MW-Microwave Sintering

Mg/ β -TCP composites with 0.5, 1, 1.5% reinforcement was studied for mechanical strength and corrosion property. Addition of β -TCP increased the compressive strength by 53%, yield strength by 34% and compressive fracture strain by 22%. 1.5% β -TCP showed 70% reduction in the grain size and corrosion studies done in HBSS showed decrease in corrosion rate compared to pure magnesium (Parande *et al.*, 2016). Comparison of MgO surface modified β -TCP and unmodified β -TCP addition with Mg-3Zn-0.8Zr alloy showed increase in the compressive strength and decrease in the corrosion rates for modified β -TCP reinforcement composites. There was no significant difference in the cell viability and cell proliferation for both the composites (Zheng *et al.*, 2017).

Mg reinforced with 20 vol% SiO_2 showed reduced grain size and decreased corrosion rate and good mechanical strength (Parande *et al.*, 2016). Mg reinforced with hollow nano SiO_2 particles of concentration 0.5, 1, 1.5% showed decreased grain size and increased mechanical strength. The in vitro cytotoxicity results showed increased cell proliferation and cell viability for 0.5% and 1% SiO_2 reinforcement. Addition of SiO_2 reduced the corrosion rate compare to pure Mg.

Conclusions

A biomaterial is any substance (other than drugs), natural or synthetic, that treats, augments, or replaces any tissue, organ, and body function. Biomaterial selection is one of the most challenging issues due to crucial requirements and biocompatibility, so it has been of major interest to material designers in recent years. This review of metal matrix composites targeting biomedical applications has attempted to demonstrate the very significant progress that has been made with the use of advanced materials such as magnesium within the human body. The present study reviewed the currently used metal matrix composites for various biomedical applications. Metals are susceptible to degradation by corrosion, a process that can release by-products that may cause adverse biological responses. Ceramics are attractive as biological implants for their biocompatibility. The studies, for example, have shown that alumina with high mechanical strength show minimal or no tissue reaction, nontoxic to tissues and blood compatibility tests were also satisfactory. Carbon with similar mechanical properties of bone is an exciting candidate, for it elicits blood compatibility, no tissue reaction and nontoxicity to cells. The integration of biocompatible metals with ceramics and non-metals such as mentioned above can lead to superior implants with enhanced performance. Innovations in the composite material design and fabrication processes are raising the possibility of realizing implants with improved performance in very near future. However, for successful applications, surgeons must be convinced with the long term durability and reliability of composite biomaterials. In the past, success of materials in biomedical applications was not so much the outcome of meticulous selection based on biocompatibility criteria but rather the result of serendipity, continuous refinement in fabrication technology, and advances in material surface treatment. In the present and future, selection of a biomaterial for a specific application must be based on several criteria. Biocompatibility is the paramount criterion that must be met by every biomaterial. Medical research continues to explore new scientific frontiers for diagnosing, treating, curing, and preventing diseases at the molecular/genetic level. This review should be of value to researchers who are interested in the state of the art of biomaterial development and selection. In the future, we can anticipate seeing novel composite biomaterials that will enhance the comfort levels of patient. Therefore, it is vital to accentuate the need for precise studies that will determine the behavior of these novel materials prior to their clinical use and determining an approach to improve the biocompatibility (i.e., biological reactions) that occur instantly after implantation. However, close alliance between surgeons, biologists and engineers is vital in order to attain success with the challenging future of joint replacements.
